Title: A novel role of Nonsense-mediated mRNA decay in neurodevelopment

Authors: M. HARRISON, Y. ZHOU, C. HUANG, M. LI, *Y. MAO
Biol., PSU, State College, PA

Abstract: Nonsense-mediated mRNA decay (NMD) is a well-known RNA surveillance mechanism that ensures the speedy degradation of mRNAs carrying premature termination codons (PTCs). This mechanism relies on several key exon junction complex (EJC) factors to distinguish PTC from the normal stop codon. But how this mechanism involves in brain development is not clear. Strikingly, mutations in EJC factor like Upf3b have been reported to cause X-linked mental retardation and autism. This strongly indicates that NMD may be a novel pathway that involves in mental retardation. We identify that a key EJC factor is required for neural progenitor proliferation. It binds to several genes involved in the Wnt pathway, and activity dependent genes that are important for neuroplasticity. In this study, we use mouse models to examine NMD function in neurodevelopment, and how it may affect behavior. Studying these mechanisms will provide insights into the causes of mental retardation and eventually lead to new therapeutic strategies for neurodevelopmental illnesses.

Title: Dmbx1 is required for cell cycle progression of retinal and tectal progenitors during neurogenesis in zebrafish

Authors: *L. WONG, V. TROPEPE
Dept. of Cell & Systems Biol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Neurogenesis is a process by which progenitor cells proliferate and subsequently undergo terminal differentiation to become various subtypes of neurons and glia. Cell cycle duration of these progenitor cells is crucial for regulating the growth (through proliferation) and cell specification (timing of cell cycle exit) in order to generate regional diversity in developing neural tissue. A key regulator of cell cycle progression of progenitor cells in the zebrafish retina and brain is a transcription factor called diencephalon/mesencephalon homeobox 1 (*dmbx1*). Loss of function of *dmbx1* using antisense morpholino oligonucleotides showed that progenitor cells in the retina and the optic tectum were progressing through the cell cycle at least 5 times slower in the absence of *dmbx1*. As a result, most of these progenitors were still cycling and unable to differentiate on time. In the present study we determined that the expression of *cyclinD1*, which is an important factor that promotes G1 to S transition and guides the cell to re-enter the cell cycle, was sustained in progenitor cells with reduced *dmbx1* levels. This finding suggested that Dmbx1 might repress *cycinD1* expression and allow cells to become post-mitotic and undergo differentiation. By knocking down *cyclinD1* and *dmbx1* simultaneously, we showed that cells were now able to exit the cell cycle and differentiate. We are testing the hypothesis that Dmbx1 is a direct transcriptional repressor of *cyclinD1*. Together, our findings highlight an important relationship between homeobox related transcription factors and the cell cycle machinery in the regulation of the timing of neurogenesis.

Title: FoxM1 is involved in interkinetic nuclear migration by controlling the length of cell cycle in the developing telencephalon

Authors: *X. WU, X. GU, Y. JIANG, X. HAN, Y. YUAN, Y. WANG, C. ZHAO
Neurodevelopment Lab., Inst. of Life Sci., Jiangsu, China

Abstract: During telencephalic development, interkinetic nuclear migration (INM) is a remarkable feature of neuroepithelium which is designed to make full use of germinal zone and maximize its output. By this way, the neuroepithelium can generate such a great number of new born neurons that make up the entire cerebral cortex. The migration of nuclear of apical progenitors (APs) is reported to be highly related with cell cycle, however the detailed mechanism between INM and cell cycle regulators has not been revealed. Here we first report that conditional disruption of the key cell cycle regulator FoxM1 in dorsal telencephalon results in abnormal INM and affect the transition from apical to basal progenitors by controlling the cell cycle length.

In this study, we first examined the expression of FoxM1 by in situ hybridization and found that FoxM1 was specifically expressed at the germinal zone of the telencephalon during embryonic development. Conditional disruption of FoxM1 in developing dorsal telencephalon by crossing FoxM1fl/fl mice with Emx1-Cre results in decreased proliferation of APs. Meanwhile the basal-to-apical INM is observed to be slowed-down, indicating the S or G2 phase may be affected. We further measured the length of S phase by 2h IdU and 0.5h BrdU double labeling, and found that in control the length of S phase was about 5.5 hour long, whereas lengthened to 8 hours in FoxM1 cko. More cells are observed to be remained in the cell cycle when a 14 hours-BrdU labeling was preformed at E14.5, which is consistent with the slowed INM. Moreover, among PH+ M phase cells, the percentage of PH3+ Tbr2+ basal progenitors is increased in FoxM1 cko when compared to that of control. These results indicate that ablation of FoxM1 slows INM by lengthening cell cycle and may play an important role in the transition from APs to BPs. In brief, FoxM1 is required for INM of APs in the developing telencephalon and involved in the neuron differentiation. Further studies are needed to elucidate the molecular mechanisms.

Abstract: The role of long noncoding RNAs (lncRNAs) in cellular development and regulatory processes are remained under-characterised. To date, only a handful of functionally characterised lncRNAs, such as *Xist*, *Evf-2*, *Air*, *HOTAIR* and *Kcnq1ot1*, were reported to have significant regulatory properties during development. In this study, we demonstrated the expression of multiple overlapping sense and natural antisense transcripts (NATs) at the *Sox4* gene locus in the *Mus musculus* C57BL/6 (mouse) brain. These NATs were spatiotemporally regulated throughout cerebral corticogenesis and formed dsRNA aggregates in the cytoplasm of brain cells with the *Sox4* mRNAs. The dsRNAs formation, however, did not alter the level of *Sox4* sense expression at RNA or protein level. Instead, the dsRNA served as a template to produce a novel endogenous siRNA (endo-siRNA), whose biogenesis is Dicer1-dependent. The endo-siRNA is expressed in the marginal and germinative zones of the developing and postnatal mouse brains suggesting a specific role in neurogenesis. To our knowledge, this is the first demonstration in the mammalian system that sense-NATs serve as Dicer1-dependent templates in the cytoplasm to produce an endo-siRNA. The finding will change the way we interpret these emerging class of noncoding RNAs and may explain the large proportion of uncharacterised biogenesis of various nontypical noncoding small RNAs in the mammalian system especially in neural plasticity.

Title: Nox4-generated superoxide drives angiotensin II-induced neural stem cell self-renewal

Authors: *W. ZAWADA[1], E. TOPCHIY[3], E. PANZHINSKIY[3], S. W. BARGER[1,4], M. DAS[2]
[1]Geriatrics - The Reynolds Inst. on Aging, [2]Med., Univ. of Arkansas For Med. Sci., Little Rock, AR; [3]Univ. of Wyoming, Laramie, WY; [4]Grecc, Central Arkansas Veterans Healthcare Syst., Little Rock, AR

Abstract: Although reactive oxygen species (ROS) play an important role in neural development and stem cell responses in the adult CNS, the mechanism by which ROS affect neural stem cell (NSC) self-renewal is poorly understood. Because angiotensin II (Ang II) has been reported to increase numbers of neuronal precursor cells, we have hypothesized that Ang II drives NSC self-renewal by stimulating production of non-toxic levels of superoxide that serve as pro-proliferative signals. To address our hypothesis, we have modeled self-renewal in a murine neural stem cell line (C17.2). Addition of Ang II (100nM) to these NSC cultures stimulated superoxide production as detected by an increase in dihydroethidine (DHE) fluorescence. Significant elevation in superoxide was first observed one hour following stimulation with Ang II and returned to baseline by 24 hours. By 48 hours, a single treatment with Ang II doubled the number of NSCs in the culture and an antioxidant N-acetyl-cysteine (NAC) blocked this Ang II-induced response, a finding consistent with superoxide being responsible for the observed

increase in proliferation. Confocal microscopy using DHE and a mitochondrial marker (MitoTracker) revealed that C17.2 cells have not one, but rather two major sources of ROS with distinct sub-cellular localizations. These ROS sources were found to be either mitochondrial or extramitochondrial; indicating that in addition to superoxide production in the mitochondria, membrane bound NADPH oxidase might be responsible for the extramitochondrial generation of ROS. Although we have identified NADPH oxidase catalytic subunits Nox3 and Nox4 to be constitutively expressed in these cells, Nox4 mRNA was more abundant. Angiotensin II increased synthesis of Nox4 protein, whereas siRNA targeting Nox4 reduced Nox4 protein levels back to baseline and abolished Ang II-induced ROS production and the proliferative response. Our findings suggest that Ang II-induced proliferation of NSCs requires Nox4-generated superoxide. This mechanism might be important for neurogenesis during brain development as well as during disease states affecting the nervous system.

Title: mTOR signaling mediates GSK-3 regulation of neural progenitor proliferation in the developing brain

Authors: *M. KA, R. TELFER, W.-Y. KIM
Developmental Neuroscience, Munroe-Meyer Inst., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Recent studies have shown that glycogen synthase kinase-3 (GSK-3) is a master molecule in the regulation of neural progenitor proliferation and neurogenesis during nervous system development. However, it remains unclear what downstream mechanisms mediate the activities of GSK-3 in neural progenitors. Here, we show that the mammalian target of rapamycin (mTOR) signaling plays an important role as a downstream of GSK-3 in cortical progenitor regulation. First, we discovered that GSK-3 controls mTOR activity in neural progenitors. Deletion of GSK-3 increases phosphorylations of 4EBP1 and S6 proteins, markers for mTOR activity, while overexpression of GSK-3 decreases the phosphorylations. Then, we generated and characterized a conditional mutant mouse in which mTOR is deleted in neural progenitors in the developing nervous system. Genetic ablation of mTOR leads to abnormal

progenitor development. There are decreases in progenitor proliferation and neurogenesis in the developing brain. Finally, we found that knockdown of mTOR activity suppresses the hyperproliferation of neural progenitors induced by GSK-3 deletion. Together, these findings reveal that GSK-3 functionally interacts with mTOR signaling and this interaction is important in neural progenitor regulation during brain development.

Title: Role of DPD in the metabolism of embryonic human brain derived cells

Authors: *K. DANIELYAN[1], O. MANUKYAN[2], T. MANUCHARYAN[2], R. ABRAHAMYAN[3], A. GALOYAN[1]
[1]H Buniatian Inst. of Biochem., H. Buniatian Inst. of Biochem., Yerevan, Armenia; [2]Biochem., Yerevan State Univ., Yerevan, Armenia; [3]Republican Maternity Hosp. , Inst. of Perinatology, Obstetrics and Gynaecology, Yerevan, Armenia

Abstract: Background. Previously by the utility of Allopurinol, classical inhibitor of Xanthine Oxidoreductase activity (EC 1.17.3.2), one of the last enzyme in the cycle of purines' catabolism, we have delineated the role of the last one in the processes of human brain E90 derived cells' proliferation and development (1). Dihydropyrimidine dehydrogenase (DPD; EC 1.3.1.2) catalyzes the initial and rate-limiting step in the catabolism of the pyrimidine bases - uracil and thymine. In our current work by the treatment of primarily human embryonic brain cell culture with the DPD inhibitor - Captopril we have estimated the metabolic activity of cultured cells by means of measurement of deposited amino acids pool.
Methods. We have used described by M.P. Mattson and B. Rychlik (2), method with some modifications. There was used the media with the d-Biotin, Catalase, L-Carnitine HCl, Corticosterone, Insulin, Progesterone, Putrescine, Superoxide Dismutase, DL Alpha-Tocopherol etc. Brain of the embryos was obtained from abortion material of the E90 fetuses. All procedures with the utility of biomaterials were carried out in accordance with the Declaration of Helsinki.

The statistics of the obtained results were calculated by the utility of t-student test and were considered significant if $p< 0.05$ (presented data are introduced as SEM). The amino acid pools was estimated by the classical Ninhydrine reaction method. Cells were grown over the 7 days with/without treatment of Captopril.
Results. In contrast to the control group the amino acid pool in the cells treated over 7 days with the Captopril was higher in statistically significant way (10.67 ± 0.02 vs 15.13 ± 2.43, $p<0.05$). Further addition of NADH, coenzyme of DPD didn't initiate the increase of amino acids quantity not in the control groups of the cells neither in the Captopril treated cells whereas addition of the Captopril into the final reaction mixture increases the quantity of amino acids in the control group in contrast to the Captopril treated group of the cells (12.22 ± 0.39; 13.86 ± 4.93; $p< 0.05$ after comparison with their above mentioned controls.
Conclusion. Treatment of the primerely human brain derived cells culture with the DPD inhibitor Captopril over 7 days initiates the increase in the amino acids pool.

Title: Pannexin 1 regulation of neurogenesis

Authors: L. E. WICKI-STORDEUR, A. D. DZUGALO, R. PRAGER, R. M. SWANSBURG, *L. SWAYNE
Med. Sci., Univ. of Victoria, Victoria, BC, Canada

Abstract: The ventricular zone of the postnatal brain contains unspecialized neural stem cells. Through a complex developmental process initiating with these unspecialized cells, new neurons

are produced. This series of dynamic changes in cellular behaviours, collectively termed neurogenesis, is essential for the development of social memories and behaviours and also plays an important role in brain repair following injury. Ion channels are emerging as key regulators of this process. We recently detected pannexin 1 (Panx1) ion and metabolite-permeable channels in neural stem and progenitor cells (Wicki-Stordeur et al. Neural Development Mar 29;7(1):11). By manipulating Panx1 expression and activity we uncovered its important impact on cell proliferation. Panx1 mediates the release of adenosine triphosphate (ATP), which in turn, activates purinergic (P2) receptors to stimulate cell proliferation. To build on this foundational work, and expand our understanding of Panx1 regulation of neural stem and progenitor cell proliferation, we then identified protein interaction partners using an unbiased proteomics approach. Here we explore how these data have provided further insight into the role of Panx1 in neural stem and progenitor cells. As these special cells are highly responsive to neurological injury and disease, and are gaining attention as putative targets for brain repair, understanding the fundamental role of Panx1 channels in neural stem cells is of critical importance for brain health and disease.

Title: From neonate to adult: Restricted phenotypic potential of newly born striatal neurons.

Authors: *J. WRIGHT, L. H. THOMPSON
Neurodegeneration, Florey Neurosci. Inst., Melbourne, Australia

Abstract: Substantial advances have been made in the last decade on our understating of the basic physiology underlying neurogenesis in the postnatal mammalian brain. The bulk of the work in this area has been based on analysis of the adult brain. Relatively less is known about the capacity for neurogenesis in specific structures within the neonatal brain. Here we demonstrate that the production of medium spiny striatal projection neurons (MSNs) in the striatum extends into the early neonatal period under normal physiological conditions in the rat brain, with low but stable contributions of striatal interneurons during this time-period. Using retroviral labeling, we further show how MSNs born neonatally, correctly acquire their axonal targets in the globus

pallidus and midbrain. These data provide evidence of latent MSN development in the neonatal striatum post-embryogenesis.
It has been recently shown that upon damage to the striatum as seen in stroke and Huntington's disease models, migratory neuroblasts born from the sub-ventricular zone (SVZ) lining the lateral ventricles are redirected into the lesioned striatum and mature into neurons. Whether adult neurogenic niches in the SVZ maintain the phenotypic plasticity as seen in the early neonatal brain and hence are able to contribute new MSN neurons to the damaged striatum remains controversial. This repair mechanism provides minimal replacement of lost neurons due to poor long-term survival. Therefore, in an excitotoxic forebrain injury model in adult rats, I have utilized two neurotrophic factors GDNF and the newly defined neurotrophic factor 'Meteorin' in an attempt to increase cell survival and migration of newly-born cells into the damaged striatum. In line with previous studies, GDNF lead to an increase in mature neurons 6 weeks post-injury, whilst Meteorin increase neuroblast migration into the damaged striatum. However, in all circumstances including lesion alone, no newly-born MSNs were found in the striatum only Calretinin+ interneurons, illustrating that phenotypic plasticity present in early neonatal SVZ neurogenic precursors is lost in the adult.

Title: Superior temporal sulcus activity to unexpected goal-directed motion decreases longitudinally in neurotypical children

Authors: A. AHMED, *B. C. VANDER WYK
Child Study Ctr., Yale Univ., New Haven, CT

Abstract: Objectives: To investigate longitudinal neurodevelopmental trends in social cognition using functional magnetic resonance imaging (fMRI).
Methods: Seventeen typically developing children (7 males, 10 females) participated in two fMRI sessions approximately 1 year apart. These longitudinal subjects had a mean age of 11.69 years at their first observation and 12.94 years at their second observation. At each visit, children were shown a 6'16'' fMRI paradigm consisting of a human actor who displays positive affect

(smile) or negative affect (frown) towards one of two cups on the screen. The actor then reaches and grabs one of the two cups in either a congruent or incongruent fashion. Congruent trials were defined as those that matched the displayed intention; the actor reached for the same cup if she displayed positive affect or the opposite cup if she displayed negative affect. Action did not match intention in the incongruent trials; the actor reached for the same cup if she displayed negative affect, or the opposite cup if she displayed positive affect. One full run consisted of 32 trials.
Regions-of-interest in the right and left superior temporal sulcus (STS) and the right dorsolateral prefrontal cortex were created using an independent sample of adults and children who viewed the same imaging paradigm. These functionally-defined regions represent significant clusters of activation that significantly differentiated incongruent and congruent conditions. Waveforms from these regions were extracted within the longitudinal sample and the peak response was defined as activation at 10 seconds after stimulus onset relative to initial activation.
Results: We investigated how the difference between incongruent and congruent conditions varied across observations. Peak brain responses in the left STS showed a significant difference between observations ($t = 2.325$, $p = 0.027$; mean at time 1 = +0.297, time 2 = -0.076). The right STS showed a similar decreasing trend but did not reach statistical significance ($t = 1.333$, $p = 0.192$; mean at time 1 = +0.216, time 2 = -0.012). Furthermore, the aggregate response to motion (the average of peak responses in both conditions) did not significantly differ between observations.
Conclusions: Preferential activation to incongruent stimuli in the left STS showed a drop-off leading to preferential activation to congruent stimuli between the initial viewing of the stimulus and a second viewing approximately one year later. This suggests that the left STS may be more sensitive to developmental changes than the right STS, and that these changes result in diminished peak brain responses to incongruent goal-directed motion.

Title: Functional imaging in the zebrafish optic tectum reveals emergent properties associated with visual motion processing

Authors: *P. HUNTER, A. S. LOWE, I. D. THOMPSON, M. P. MEYER
MRC Ctr. for Developmental Neurobio., King's Col. London, LONDON, United Kingdom

Abstract: In zebrafish the optic tectum is the principal target of retinal ganglion cells (RGCs) and is required for visually driven behaviours such as prey capture and predator avoidance. However, we know little about the specific computations that the tectum performs in order to elicit these behaviours. This is due, in large part, to the fact that little is known about the type of visual information that is delivered to the tectum by RGCs. We have previously addressed this by using *in vivo* functional imaging and a drifting bar stimulus to categorise orientation- and direction-selectivity in the population of RGC inputs to the tectum. Here we begin to use this functional description of retinotectal inputs as a basis for asking how these inputs are processed in the postsynaptic tectal neurons.
Using bulk loading of tectal neurons with the calcium indicator, Oregon Green BAPTA 488-AM, we apply the same drifting bar stimulus and unbiased, voxel-wise analysis strategy to characterise the population of tectal cells. Individual cell somas were automatically delineated by clustering ‘like’ voxels: neighbouring voxels that exhibit comparable descriptive statistics. The normalised vector sum and 1-circular variance defined cells as direction- and orientation-selective cells respectively. Cumulative statistics across multiple fish identified two populations of orientation-selective tectal cells that match those present in the population of RGC inputs. However, we identify a population of direction-selective tectal neurons that are tuned to head-to-tail motion - a response type not present in the RGC input population. To the best of our knowledge this is the first emergent property associated with tectal circuits in zebrafish.
By co-registering data from multiple larvae we can generate composite, functional parametric maps to reveal the spatial organisation of direction- and orientation-selective tectal cells. Registering these maps with similar parametric maps of the RGC inputs will show whether the retinotectal biases evident in the input populations are mirrored in the postsynaptic tectal cells. The behavioural significance of these emergent properties and functional architecture is something that can be addressed in the future using zebrafish as a model system.

Title: Investigating the functional presynaptic variability of single cells in the larval zebrafish

Authors: *A. WALKER, M. P. MEYER
MRC Ctr. for Developmental Neurobio., King's Col. London, London, United Kingdom

Abstract: A major determinant of functional synaptic strength is the probability of Ca2+-induced neurotransmitter release from a presynaptic terminal. Release probabilities at individual presynaptic terminals can be diverse, even when they belong to the same axon. It is important to understand the underlying causes of synaptic heterogeneity as ultimately these determine the reliability, flexibility and diversity of information transfer in the brain. Here we use expression of a presynaptically targeted, genetically encoded calcium indicator (SyGCaMP3) in single zebrafish retinal ganglion cells (RGCs) to study presynaptic functional heterogeneity across an axonal arbour in vivo. Because the visual system of zebrafish is functional well before the structural development of visual circuits is complete we can use visual stimulation and functional imaging to characterise synaptic properties as RGC axonal arbours develop. Our strategy provides an opportunity to study, in parallel, the development of cell-wide tuning properties of single, identified, RGCs in vivo. By expressing SyGCaMP3 in individual RGCs we are able to target direction- and orientation-selective cells and record visual stimulus-induced calcium responses in discriminated presynaptic boutons. Thus, we can record the magnitude of responses of all presynaptic sites belonging to a single neuron, and assess the spatial organisation by synaptic weight across the axonal arbour. By imaging the same cell throughout development we can not only determine how direction- and orientation-selectivity emerges, but also how synapse functional heterogeneity changes as a function of developmental stage and axon arbour complexity.

Title: The rapid recovery of visual acuity promoted by short periods of darkness in amblyopic kittens can be accompanied by the passive acquisition of stereopsis.

Authors: *D. E. MITCHELL[1], K. DUFFY[1], K. HOLMAN[1], K. MACNEILL[2]
[1]Dept Psychology, Dalhousie Univ., Halifax, NS, Canada; [2]Orthoptics, IWK Hosp., Halifax, NS, Canada

Abstract: Earlier we demonstrated (O'Leary et al, *Frontiers Syst. Neurosci* 6: 22, 2012) that short periods of darkness reduce labeling for neurofilament, a cytosketon protein that forms a stable intracellular scaffold and supports neuron structure. In some respects, the change in neurofilament mimics a prior developmental stage. Could this alteration in cytoskeleton protein signal an increased level of plasticity and a greater capacity for recovery from amblyopia?
To investigate this issue, 9 kittens were rendered amblyopic by monocular deprivation from either P7 or P30 until P37. Following introduction of binocular vision at P37, kittens were placed in darkness for 10 days (a dark pulse) either immediately after MD (ID Group; N=4) or 5-8 weeks later (DD Group; N=5). Acuity measurements for gratings were made both binocularly and monocularly by means of a jumping stand. Once acuity had stabilized for at least 2 months, at which time no animal evinced any amblyopia, monocular and binocular measurements were made of depth discrimination thresholds with stimuli that presented sparse monocular depth cues (Mitchell et al, *Perception* 8: 389-396, 1979).
Kittens from the ID group (dark pulse immediately after MD) initially appeared blind in both eyes. Form vision returned in 1- 3 days after which the visual acuity of each eye improved gradually in tandem to normal levels in 2 months. *Amblyopia never developed.* The severe amblyopia that developed in animals from the DD group disappeared rapidly in 5-7 days following the dark pulse. By comparison to animals from the ID group, the dark pulse had no effect on the acuity of the nondeprived eye indicating a short critical period for the effects of a dark pulse on vision (<70 days). For 5 animals, binocular thresholds were an order of magnitude or more better than monocular thresholds; the large binocular superiority makes it likely that they possessed at least local stereopsis. As the binocular depth thresholds of the 4 remaining animals were no better than monocular thresholds, it is likely that they were stereoblind. There was no indication that animals from the ID group, who never developed amblyopia, were more likely to develop stereopsis than those in which the dark pulse was delayed.
Although it is tempting to attribute the rapid changes in acuity and the acquisition of stereopsis to cytoskeletal modification, darkness likely exerts other effects including changes in the excitatory-inhibitory balance in the visual cortex. The dramatic beneficial improvement in visual

acuity and stereoscopic vision suggests that complete elimination of light to both eyes for 10 days may facilitate current behavioral therapies for amblyopia.

Title: Peeking through eggshells - How does light induce visual asymmetries in pigeons before hatch?

Authors: *F. STROECKENS, O. GUNTURKUN
Inst. for cognitive Neuroscience, Biopsychology, GAFO 05/622, Ruhr-University Bochum, Bochum, Germany

Abstract: Pigeon embryos take an asymmetrical prehatch position with the right eye pointing towards the semi-translucent shell, resulting in a higher level of visual stimulation of the right eye. This asymmetric light stimulation leads to the development of visual pathway asymmetries and lateralized visual behavior. However, at this stage of development retinal photoreceptors are still not functional, meaning light stimuli must be perceived by a different receptor. It is known that beside the classic rod/cone photoreceptor system a second instance of photoreceptive pigments exists inside retinal ganglion cells (RGC's). Those cells, localized in the ganglion cell layer mature early during embryonic development and establish their first contacts to the optical tectum before the critical phase of asymmetry induction occurs. Therefore, those photoreceptive RGC's are very likely the photoreceptive structure inducing lateralization. Studies in mammals and avian species show, that Cryptochrome 1b (Cry1b), thus far known to be responsible for entrainment of the “inner clock” during circadian rhythm but without any image giving function is expressed in RGC’s. We assume that Cry1b-containing RGC's are also responsible for inducing asymmetry formation during embryonic development in pigeons. To verify this assumption, we used an avian specific Cry1b antibody to label possible expressions sides in retinae of adult, post hatch and embryonic pigeons to test; 1) if Cry1b is in general expressed in pigeons; 2) if Cry1b is expressed during the critical time of asymmetry induction during and shortly after embryonic development. We found, that Cry1b is expressed in a subset of RGC’s and few displaced ganglion cells in adult, post hatch and embryonic pigeons. However,

expression in post hatch and embryonic pigeons was weaker in comparison to adults. Our results show that Cry1b is expressed in the pigeon's retina and is present during the critical period of asymmetry induction. Therefore Cry1b is a feasible candidate for the induction of visual asymmetries in pigeons. We currently plan to double label Cry1b positive cells in light and dark incubated embryonic pigeons with activity markers to show an activation of these cells towards light as well as tracing study to investigate projection targets of Cry1b containing RGC's. In combination with behavioral asymmetry testing of animals which were raised under wavelength only activating Cry1b, this might finally deliver the mechanism initializing visual asymmetries in birds.

Title: Evaluation of bmp4 signaling in early eye development in mouse embryo culture system

Authors: *V. K. KALASKAR[1], J. D. LAUDERDALE[2]
[1]Biomed. & Hlth. Sci. Inst., [2]Cell. Biol., Univ. of Georgia, Athens, GA

Abstract: Embryos overexpressing (18 copies) 'pairedless' Pax6 (Pax6ΔPD), an isoform of Pax6 gene, exhibit lens degeneration with concomitant upregulation of Bmp4 in the optic cup and PSMAD -1/5/8 expression in the lens tissue. We used a mouse embryo culture system to evaluate the role of BMP4 signaling in these tissue interactions. Wild-type embryos were CD1-C57BL/6J. Embryos with 8 or 18 copies of Pax6ΔPD express green fluorescent protein (GFP) under the control of Pax6 promoter. Embryos at E10.5 were cultured in a standardized serum free stem cell culture medium in an oxygenated rolling culture system. BMP4 or BSA treated affi-gel beads were implanted adjacent to the optic cup. Wild-type E10.5 mouse embryos cultured for 24 to 36 hours showed morphological development and tissue specific gene expression in the ocular tissue consistent with early eye development. BMP4 bead implantation dorsal to the optic cup resulted in upregulation of PSMAD-1/5/8 expression in the surrounding mesenchymal cells and in the dorsal optic cup. BMP4 resulted in expansion of the dorsal region

and under-development of the ventral region of the optic cup and affected the expression tissue specific genes like Pax6. Implantation at 29 - 30 somite stage (E10) inhibited the initiation of pigmentation, while at 34 - 35 somite stage (E10.5) resulted in decreased pigmentation in the retinal pigmented epithelium (RPE). Our results indicate that, BMP4 signaling regulates pigmentation in the RPE in a stage-dependent manner and affects the dorsal-ventral patterning of the optic cup. We believe this mouse embryo culture system will be useful for laboratories needing to utilize whole embryos to study signaling interactions important in early eye development.

Title: Inter-tectal connections mediate visual avoidance behavior in Xenopus

Authors: *A. C. GAMBRILL, W. SHEN, H. T. CLINE
The Scripps Res. Inst., La Jolla, CA

Abstract: Interhemispheric connections play an important role in mediating activity in multiple experimental models. The existence of axons crossing the midline from one lobe of the optic tectum to the other in Xenopus has been anecdotally documented; however the function of these inputs is still unknown. While retinal inputs to the optic tectum are almost exclusively contralateral, we find that neurons in the optic tectum send axon outputs to contralateral tectum and that disruption of the rostral-posterior portion of these commissures abolishes visually-guided avoidance behavior, indicating a critical role for these connections in processing visual information. The optic tectum, the equivalent of the mammalian superior colliculus, receives and integrates multimodal sensory inputs. To determine the role of inter-tectal connections in the development of the neural networks which shape visual behavior, and in the integration of information from multiple modalities, we have undertaken an anatomical and electrophysiological characterization of inter-tectal connections. We show that these processes are distributed throughout the rostrocaudal axis of the optic tectum, and that a significant fraction of neurons in the tectum receive either direct or indirect input from the contralateral lobe. Stimulation of ipsilateral tectum using a bipolar electrode can evoke synaptic responses in the

contralateral lobe of the optic tectum. These synaptic responses are comprised of both excitatory currents, which are sensitive to blockade with AMPAR- and NMDAR- selective antagonists (57.7 +/- 7.5% blockade when recorded at +40mV in the presence of 2uM NBQX and 50uM APV), as well as inhibitory currents, which are sensitive to blockade with GABA-A-antagonists (61.6 +/- 5.2% blockade when recorded at 0mV with 40uM picrotoxin). We have characterized these responses from stage 44 to stage 48, a developmental window critical for synaptic and network maturation in Xenopus. We conclude that through a combination of excitatory and inhibitory input, inter-tectal fibers play a critical role in mediating visual behavior.

Title: Developmental changes in inter-subject correlation of cortical activity.

Authors: *Y. LERNER[1], S. SCHERF[2], M. KATKOV[3], M. BEHRMANN[4], U. HASSON[5]
[1]Dept. of Psychology, Tel Aviv Sourasky Med. Ctr., Tel Aviv, Israel; [2]The Pennsylvania State Univ., Philadelphia, PA; [3]Weizmann Inst. of Sci., Rehovot, Israel; [4]Carnegie Mellon Univ., Pittsburgh, PA; [5]Princeton Univ., Princeton, NJ

Abstract: In typical adults, a surprising amount of shared responses across different individuals is found during free viewing of real life movies (Hasson et al., 2004). These findings indicate that a large extent of human adult cortex is stereotypically responsive to naturalistic audiovisual stimuli and lead to natural questions about how these shared responses emerge developmentally. To investigate this issue, we used functional magnetic resonance imaging (fMRI) to measure the inter-subject correlation of neural responses evoked by an 11-minute child appropriate movie

('Escape to Witch Mountain'), in children (ages 9-14), adolescents (ages 15-19) and adults (ages 20-32). The resulting fMRI time course acquired from each brain area in each individual was used to compute within-age group correlations (children-children, adolescents- adolescents, adults-adults) and between-age group correlations (children-adults, adolescents-adults). The analysis was performed separately in each area defined by the cluster analysis of local responses, without the need to hypothesize a priori about the differences in the response patterns across age groups. The within-age group correlations assess whether each brain area responds reliably to the movie within a given age group, where the comparison to the adult responses assesses whether each brain area responds in a stereotypical “adult-like” pattern across age groups. Our results showed that the responses in primary sensory areas in children and adolescents are very similar to the responses observed in the adults, suggesting that these areas functionally mature at early stages of the development. However, some regions exhibited higher within-age correlation in the children and/or adolescents than within the adults. We plot the brain responses across whole cortex and identify the different patterns of maturation through which these areas evolve. These findings reflect quantitative changes in the widespread cortical networks that support emerging stereotypical responses to naturalistic stimuli and will have important implications for future studies of cortical development.

Title: Presynaptic SNAP-25b regulates the firing size of retinal waves during development

Authors: *Y.-T. HSIAO[1], P.-C. HUANG[1], Y.-C. CHEN[1], S.-Y. KAO[1], C.-T. WANG[1,2,3,4]
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., [4]Genome and Systems Biol. Program, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: SNARE complex plays an important role in neurotransmitter release. SNAP-25 (SN25), one of three SNARE proteins, can be phosphorylated by PKA and PKC, providing the

versatility in the mechanisms regulating neurotransmitter release. Our previous studies in PC12 cells suggested that SN25b phosphorylation by PKA and PKC differentially regulates fusion pore kinetics during Ca^{2+}-dependent exocytosis. However, it is unclear whether SN25b in presynaptic neurons could further influence the large-scale network activity. Retinal waves, patterned spontaneous activity in the developing binocular retina, are initiated by neurotransmitter release and thus serve as a useful model for the study of synaptic transmission on a large scale. In this study, we determined whether SN25b could modulate the characteristics of retinal waves. Wild-type SN25b (wt-SN25b) was specifically overexpressed in presynaptic starburst amacrine cells (SACs) of neonatal rat retinas. By combining molecular perturbation and live calcium imaging, we examined the changes of wave properties in the postsynaptic retinal ganglion cells (RGCs). Wave frequency remained the same by overexpressing wt-SN25b in SACs compared to control, suggesting that the expression level of SN25b in presynaptic SACs may not involve in regulating wave initiation. In contrast, both duration and intensity of single waves were significantly increased by overexpressing wt-SN25b compared to control, suggesting that SN25b overexpression in presynaptic SACs enhances wave firing size. Given that retinal waves are augmented by cAMP-PKA signaling, our results thus suggest that the expression level of SN25b in presynaptic SACs may up-regulate the firing size of retinal waves, possibly through phosphorylation by cAMP-PKA signaling.

Title: Cartesian and non-Cartesian contrast sensitivities are changed in acute and early malnourished children

Authors: *C. C. ALENCAR[1], N. A. SANTOS[2], L. R. G. BRITTO[1]
[1]Laboratório De Neurobiologia Celular, São Paulo, Brazil; [2]Univ. Federal da Paraíba, João Pessoa, Brazil

Abstract: Acute malnourished (AM) children present current malnutrition, resulting in normal height according to age but underweight according to height. Early malnourished (EM) children have experienced inadequate nutrition during the critical period of nervous system development, followed by nutritional recovery, resulting in a short stature according to age but normal weight according to the short stature. We measured Cartesian and non-Cartesian contrast sensitivities (CS) in sixty children of both sexes, aged 7 to 11 years-old (M=9.2, SD=.99). Twenty children were eutrophic (E) - without malnutrition, twenty were AM and twenty were EM, based on state healthcare records and Waterlow's anthropometric parameters. CS to four spatial frequencies (.25, 1.0, 2.0, and 8.0 cycles per degree [cpd]) was measured using a temporal two-alternative forced-choice psychophysical method, with mean luminance of 40.1 cd/m2. The Repeated Measure Analysis of Variance applied to the Cartesian CS showed significant differences between the groups [$F(2,57)=48.5, p<.05; \alpha=1$]. The Fisher LSD post hoc test showed that the AM children were 1.10 and 1.11 times less sensitive than the E group to the frequencies of 1.0 and 2.0 cpd, respectively. The EM group was 1.34 and 1.24 times less sensitive than the E and AM groups, respectively, to the frequency of .25 cpd; 1.60 and 1.45 to the frequency of 1.0 cpd; 1.53 and 1.37 to the frequency of 2.0 cpd. The EM children were 1.27 times more sensitive than the E group to the frequency of 8.0 cpd. The Repeated Measure Analysis of Variance applied to the non-Cartesian CS showed significant differences between the groups [$F(2,57)=13.3, p<.05; \alpha=1$]. The Fisher LSD post hoc test showed that the EM children were 1.48 and 1.35 times less sensitive than the E and AM groups, respectively, to the frequency of 8.0 cpd. The AM group was 1.12 and 1.09 times less sensitive than the E and EM groups, respectively, to the frequency of 1.0 cpd; 1.12 and 1.08 to the frequency of 2.0 cpd. These results suggest that acute malnutrition impairs CS to medium-spatial-frequencies Cartesian and non-Cartesian gratings, whereas early malnutrition impairs CS to low-to-medium-spatial-frequencies Cartesian gratings and high-spatial-frequencies non-Cartesian gratings in children. The assessment of Cartesian and non-Cartesian CS may help establish a more nuanced characterization of the effects of malnutrition on the developing visual system and aid in diagnosis, prognosis, and follow-up treatment in children who experienced malnutrition.

Title: Spontaneous retinal activity is critical for establishing the anatomical and functional organization of the lateral geniculate nucleus in the absence of eye-specific segregation

Authors: *S. W. FAILOR, B. CHAPMAN
Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: The lateral geniculate nucleus (LGN) in ferrets undergoes a series of developmental periods involving the formation of eye-specific laminae, sublaminae that receive input from ON-center and OFF-center retinal ganglion cells, and the refinement of synaptic inputs to individual geniculate cells. These developmental processes result in highly stereotyped laminar patterning (Speer et al. 2010), receptive field structures (Tavazoie et al., 2000), and retinotopy (Zahs et al., 1985). It has been well established that spontaneous retinal activity plays a role in eye-specific segregation (Penn et al., 1998; Stellwagen et al., 2002), and additionally retinotopic refinement in mice (Grubb et al., 2003); here we show that in the ferret spontaneous retinal activity plays a role in the establishment of correct retinogeniculate lamination, as well as both receptive field structure and retinotopy, when eye-specific segregation is absent.

Ferrets at postnatal day zero (P0) were monocularly enucleated to eliminate the retinogeniculate afferents from one eye. Starting at P0 the remaining eye was injected with either epibatidine (epi) or saline intravitreally every 48 hours until P10 to disrupt spontaneous retinal activity (Penn, et al. 1998; Sun et al. 2008). In epi treated enucleates the shape of the ipsilateral (ipsi) lamina failed to expand, as it normally does due to enucleation, and its borders were unrefined, whereas the contralateral (contra) lamina lacked afferents in a caudal medial region. When enucleates were allowed to recover to P25 following epi injections, abnormal lamination was again observed for both the ipsi and contra projection. In these animals the ipsi lamina was fragmented and both ipsi and contra lamina lacked the defined ON/OFF sublaminae seen in control enucleates. Adult ferrets (P60+) were anesthetized and single-unit electrophysiology recordings were carried out to characterize the functional organization of the LGN following early enucleation and epi treatment. Areas of the LGN in epi treated animals contained cells that developed abnormal receptive field size and structure, with retinotopy also being disrupted.

Our results align with previous work in supporting a role for activity in retinotopic refinement; additionally we demonstrate that activity drives the establishment of retinogeniculate lamination even in the absence of eye-specific segregation. These results suggest that activity-dependent mechanisms besides Hebbian-like axonal competition are at play during development, such as

the readout of axon guidance molecules or the competition-independent refinement and/or elaboration of retinogeniculate axons.

Title: Developmental refinement of LGN receptive fields contributes to the maturation of orientation selectivity in the cortex

Authors: *C. W. KILEY, W. M. USREY
Neurosci., UC Davis, DAVIS, CA

Abstract: In contrast to the growing number of studies providing support for the Hubel and Wiesel model of the organization of geniculocortical connections that underlie the receptive field properties of simple cells, we know relatively little about the mechanisms that guide the specificity and refinement of these connections during development. To test the hypothesis that correlation-based mechanisms may play a role, we investigated the relationship between the maturation of LGN receptive fields and the refinement of correlated activity patterns between neighboring LGN neurons. Single-unit recordings were made from small ensembles of LGN neurons in the kitten at various stages of development to compare the spatiotemporal receptive field properties of individual neurons with the patterns of the cells' correlated activity evoked by stimuli drifting at various orientations. Our results demonstrate a tight correspondence between the size and location of LGN receptive fields and the orientation tuning of their correlated activity. In particular, as LGN receptive fields mature and decrease in size, the number of neurons co-excited by a common stimulus decreases and the orientation tuning of their correlated activity sharpens. These results support the idea that the refinement of receptive fields in the LGN contributes to the development of orientation tuning in the cortex.

Title: Information processing in the optic tectum mediates collision avoidance behavior in the Xenopus laevis tadpole

Authors: *A. S. KHAKHALIN, D. KOREN, J. GU, C. D. AIZENMAN
Neurosci., Brown Univ., Providence, RI

Abstract: The optic tectum of anuran tadpoles is a main integrative sensory center in these animals, mediating orienting behaviors, such as collision avoidance, schooling, and visually-driven escape responses. While a lot is known about the development and cellular organization of the optic tectal circuitry, it is still unclear how information coming from the environment is encoded in the activity of tectal cells, and how the computations are performed.
Here we describe a collision avoidance behavior in Xenopus laevis tadpoles, and through a series of sequentially reduced preparations we illustrate the mechanisms underlying this behavior. In the first set of experiments we presented freely swimming animals with computer-generated two-dimensional objects, approaching them at either collision or non-collision trajectories. By tracking the animals, and by reconstructing the geometry of approaches, and the projections computer-generated objects would have on the retinas, we identified temporal and spatial properties of those stimuli that successfully triggered the collision avoidance response. Then, in the second set of experiments, we presented partially immobilized animals with computer generated stimuli that were projected on a microfiber screen placed near one of the eyes. The stimuli were specifically designed so that their retinal projections mimicked our reconstructions from the first set of experiments. A high speed camera was used to track the movements of the tail, and we show that different stimuli induced different sub-variants of the avoidance motor program, with different latencies, and probabilities. Finally, we presented the same set of stimuli to fully immobilized animals, recording either the spiking activity, or the inhibitory and excitatory postsynaptic currents from individual cells in the optic tectum. We show that the spatial and temporal computations that are required for the identification of behaviorally relevant stimuli start at the level of the ganglion cells in the retina, and continue in the optic tectum, where they rely on the temporal interaction between excitatory and inhibitory drive to the tectal cells.

Title: Role of SPAR3/Sipa1L3 in lens and brain development

Authors: *N. KANWAL[1], J. BOCKMANN[1], M. KÜHL[2], S. J. KÜHL[2], T. M. BOECKERS[1]
[1]Inst. of Anat. and Cellbiology, Ulm Univ., Ulm, Germany; [2]Inst. of Biochem., Ulm, Germany

Abstract: Spine associated Rap-GAP 3 is a novel, hitherto uncharacterized component of the post synaptic density (PSD). SPAR3 belongs to the SPAR family of small GTPase activators. It is well conserved among species (Rattus norvegius, Mus musculus, Xenopus laevis), and consists of 20 exons encoding 1776 amino acids in mouse.
We generated SPAR3 knockout mice to uncover the functional properties of this protein in vivo. SPAR3 mutant mice display a severe phenotype of juvenile cataract. Already during fetal development an abnormal protrusion of the lens, an altered structure of the optical cup surrounding the developing lens can be observed. Moreover, further investigation revealed an abnormal arrangement, shape, structure and packing of lens fiber cells. Interestingly, most of the lens fiber cells retain their nuclei. Known interaction partners of SPAR3 (LAPSER1, beta-catenin) and neuronal marker proteins (ßIII-Tubulin, MAP2, Synaptophysin, PSD95) are up-regulated in lenses of mutant mice, but not in the respective brain regions. Furthermore, other members of the SPAR family (SIPA, SPAR1, and SPAR2) are highly expressed in brain, but not in lenses thus implicating possible compensatory effects of these family members in brain. Taken together SPAR3 seems to have a crucial role during early lens development and that lens fiber cells in SPAR3 knockouts may lose their early differentiation path. Further investigations of our SPAR3 mutants will help to elucidate the functional aspects of this novel protein during the development of the ocular system.

Title: Synaptotagmin III regulates the firing rate of retinal waves in the developing rat retina

Authors: *S.-Y. KAO[1], Y.-C. CHEN[1], C.-T. WANG[1,2,3,4]
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., [4]Genome and Systems Biol. Program, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Binocular visual circuit refinement requires a robust patterned spontaneous activity in the developing retina (i.e. retinal waves). In postnatal rats (P0-P9), retinal waves are initiated via a subset of starburst amacrine cells (SACs) releasing acetylcholine (ACh) onto postsynaptic retinal ganglion cells (RGCs). Synaptotagmin (Syt) family serves as a calcium sensor during Ca^{2+}-regulated exocytosis to mediate neurotransmitter release. Although more than seventeen Syt isoforms have been discovered, the Syt isoform responsible for Ca^{2+}-regulated exocytosis in the initiation of stage-II waves remains obscure. Our previous findings suggested that Syt III is abundantly expressed in the RGC layer and inner plexiform layer (IPL) during the first week of postnatal rats, consistent with the developmental time course of stage-II waves. In this study, we used molecular perturbation and subsequent live Ca^{2+} imaging to determine the role of Syt III in regulating retinal waves. Whole-mount developing rat retinas (P0-P2) were transfected by the DNA vectors carrying Syt III or antisense-Syt III. Control was the vector carrying the transfection marker EGFP only. After 70 hours post transfection, spontaneous and correlated Ca^{2+} transients in the developing RGCs were imaged by the Ca^{2+} indicator fura-2 at 1 s-interval for 10 min. By calculating the interval of calcium transients associated with retinal waves, we found that inter-wave interval was significantly decreased in Syt III-overexpressing retinas compared to control. In contrast, inter-wave interval was not changed in antisense-Syt III-overexpressing retinas compared to control. Overexpressing Syt III or antisense-Syt III did not alter the duration and intensity of single waves, indicating that the firing size of retinal waves remains the same. Thus, our results suggest that Syt III regulates the firing rate of stage-II waves in the developing rat retina.

Title: Nogo-A influences the eye-specific segregation of retinogeniculate projections

Authors: *A. M. GUZIK-KORNACKA, V. E. PERNET, M. E. SCHWAB
Brain Res. Institute, Univ. of Zurich/ETH, Zurich, Switzerland

Abstract: The retinogeniculate pathway of the mouse is an excellent model to study the refinement of connections and stabilisation of axonal arbours and synapses. Before eye opening, retinal axons from the two eyes in the dorsal lateral geniculate nucleus (dLGN) undergo extensive pruning and segregate into non-overlapping territories. After eye opening, retinogeniculate synapses are further strengthened and stabilized, or pruned, respectively. Nogo-A, a potent neurite growth inhibitory protein, is highly expressed in early postnatal retinal ganglion cells (RGCs), whereas in the adult visual system it is mainly present in myelin. The developmental switch in localization of Nogo-A coincides with the maturation of retinogeniculate system. There is a growing body of evidence that Nogo-A restricts synaptic plasticity; e.g. Nogo-A/B knock out (KO) or Nogo receptor (NgR1) KO mice have been shown to possess high visual cortex plasticity in adult life, far beyond the end of the so-called critical period. Here we compared the segregation of retinogeniculate axonal terminals from both eyes between the wild type and Nogo-A KO mice. We visualised retinal axons from the two eyes by two coloured fluorescent cholera toxin subunit B tracing and analysed the segregation of eye-specific domains by two independent methods. Strikingly, in adult Nogo-A deficient mice we observed a significantly lower degree of eye-specific terminal segregation, i.e. a marked overlap of left- and right eye termination zones. Further experiments will help to answer whether the observed phenotype is due to developmental defects or to increased plasticity causing sprouting and instability of axonal arbours in the absence of the growth inhibitory cue Nogo-A.

Title: Broadening of cortical inhibition mediates developmental sharpening of orientation selectivity

Authors: *Y. LI[1,2], L. IBRAHIM[2], W.-P. MA[2], L. I. ZHANG[2], H. W. TAO[2]
[1]Los Angeles, CA; [2]Zilkha Neurogenetic Inst., University of Southern California, CA

Abstract: Orientation selectivity (OS) of visual cortical neurons is progressively sharpened during development. However, synaptic circuit mechanisms underlying the OS sharpening remain unclear. In the current study, in vivo whole-cell voltage-clamp recordings from layer 4 excitatory neurons in the developing mouse primary visual cortex revealed changes of orientation tuning profiles of their excitatory and inhibitory inputs during a post-eye-opening period when OS of their spiking responses becomes sharpened. In addition to a parallel strengthening of excitation and inhibition during this developmental period, the orientation tuning of excitatory inputs keeps relatively constant, whereas the tuning of inhibitory inputs is broadened, and becomes significantly broader than that of excitatory inputs. Neuron modeling and dynamic-clamp recording demonstrated that this developmental broadening of the inhibitory tuning is sufficient for sharpening OS. Depriving visual experience by dark rearing impedes the normal developmental strengthening of excitation, but a similar broadening of inhibitory tuning, likely caused by a nonselective strengthening of inhibitory connections, results in the apparently normal OS sharpening in excitatory neurons. Our results thus provide the first demonstration that an inhibitory synaptic mechanism can primarily mediate the functional refinement of cortical neurons.

Title: Alternative splicing of the LIM-homeodomain transcription factor Isl1 in retinal ganglion cells

Authors: *I. E. WHITNEY[1,2], B. REESE[3,2]
[1]Molecular, Cellular, and Developmental Biol., Univ. of California at Santa Barbara, SANTA BARBARA, CA; [2]Neurosci. Res. Inst., [3]Psychological & Brain Sci., Univ. of California at Santa Barbara, Santa Barbara, CA

Abstract: The LIM-homeodomain (LIM-HD) transcription factor Isl1 plays a role in the differentiation of multiple cell-types in the retina. An alternative isoform of Isl1, Isl1β, has been identified in pancreatic cells; alignment to the canonical isoform, Isl1α, reveals the absence of 23 amino acids corresponding to a protein-binding domain. This study seeks to determine the role of *Isl1* alternative splicing in the differentiation of neuronal cell-types in the mouse retina.
The pattern of *Isl1* alternative splicing across multiple tissues was determined using RT-PCR with one primer pair capable of amplifying both isoforms. Quantitative real time RT-PCR with isoform-specific primers was used to characterize expression changes in the developing retina. The translation of *Isl1* isoforms in the retina was assessed by western blotting using a commercially available monoclonal mouse antibody that recognizes both isoforms. This pan-Isl1 antibody, in conjunction with a custom-made rabbit polyclonal antibody specific to the alpha isoform, was also used with standard immunofluorescence techniques.
We found both *Isl1* isoforms to be expressed in the developing and adult mouse retina, with *Isl1α* in greater abundance. This pattern of expression was also found in other *Isl1* positive tissues, including brain and spinal cord. Quantification of *Isl1* transcript abundance revealed a progressive increase in expression differences across retinal development with *Isl1α* having a 2 (E12), 4 (E16), 5 (P1), 6 (P10) and 13 (adult) fold greater expression than *Isl1β.* We also identified two peaks in both *Isl1α* and *Isl1β* expression at E16 and P10, coincident with the genesis of *Isl1* expressing cells. The pan-Isl1 antibody recognizes two protein products differing in size by the expected 23 amino acids absent in Isl1b, confirming the presence of both isoforms in the retina at the protein level. Certain bipolar, amacrine, and ganglion cells are labeled with the pan-Isl1 antibody; while every pan-Isl1 bipolar and amacrine cell was co-localized with the Isl1-alpha antibody, a subset of pan-Isl1 RGCs were not, revealing the existence of a beta-isoform only population of RGCs. We subsequently analyzed the soma size of these pan+/alpha+ and pan+/alpha- RGCs and found the beta-only population to be restricted to RGCs of small and medium soma sizes (50-175 μm^2) and never found to be RGCs with large somas (176-300 μm^2). These results indicate possible functional differences in the Isl1 isoforms leading to the differentiation of distinct RGC types, supporting alternative splicing as a mechanism for generating neuronal diversity in the CNS.

Title: Melanopsin ganglion cells are critical for the proper development of the visual system

Authors: *J. M. RENNA[1], K. CHEW[2], G. LOEVINSOHN[1], S. WENG[1], S. HATTAR[2], D. M. BERSON[1]
[1]Neurosci., Brown Univ., Providence, RI; [2]Biol., Johns Hopkins Univ., Baltimore, MD

Abstract: Waves of correlated activity sweep across the early postnatal retina and contribute to segregation and refinement of retinofugal projections. The waves have been viewed as light-independent, as they appear before rods and cones can affect the inner retina. Amacrine cells have been thought to drive the waves, and ganglion cells to be passive recipients. However, we recently showed that, during this period, light alters both retinal waves and maturation of retinofugal projections by exciting melanopsin ganglion cells (mRGCs; Renna et al., 2011). At this age, mRGCs are excited not only by light, but by the waves themselves. Since mRGCs alter waves when excited by light, we wondered whether they might also do so in the dark, by feeding back wave-generated signals to the wave-generating network. We therefore tested whether, in the absence of light, genetic ablation of mRGCs would affect the retinal waves and the development of retinofugal projections.
We made multi-electrode array recordings in darkness from retinas of postnatal day 6 (P6) mice lacking melanopsin ganglion cells (*Opn4*$^{dta/dta}$) and matched controls (*Opn4*$^{+/+}$). Relative to controls, single ganglion cells in *Opn4*$^{dta/dta}$ mice exhibited prolonged bursting during waves (10.8% increase; $p<0.05$) and more spikes per burst (40% increase; $p<0.05$;n= 3 retinas/54 cells *Opn4*$^{dta/dta}$, and n= 3 retinas/64 cells *Opn4*$^{+/+}$). At distances greater than 600μm, pairs of cells exhibited more correlated firing in *Opn4*$^{dta/dta}$ mice relative to controls ($p<0.05$). To assess the effects of the loss of mRGCs on the ocular segregation of retinofugal projections, *Opn4*$^{dta/dta}$ and *Opn4*$^{+/+}$ mice were raised in continuous darkness. At P7, we made ocular injections of contrasting fluorescent anterograde tracers (cholera toxin B [CTB]-Alexa-488 and CTB-Alexa-594) and harvested the tissue at P8. Data were processed and analyzed as described by Renna et. al. (2011). *Opn4*$^{dta/dta}$ mice lacked a well-defined ipsilateral sector within the dLGN and

exhibited a 20% increase in the number of pixels with substantial label from both eyes ($p < 0.0001$; n= 4 *Opn4*$^{+/+}$, 5 *Opn4*$^{dta/dta}$, 10 sections/mouse/dLGN).
Retinal wave activity drives the development of the image forming visual system. mRGCs, the main conduits of input to non-image forming visual centers, are excited by retinal waves and alter retinal wave activity when depolarized (Renna et. al., 2011). Here we have shown that when mRGCs are removed from the circuit, wave activity is altered and the projections to the dLGN are less segregated. These results suggest that, even in the absence of light, mRGCs contribute to the proper development of the image-forming visual system.

Title: Preliminary study: Frontal gamma dynamics of infants

Authors: *M. BALLAN, J. H. GILMORE
UNC Chapel Hill, Chapel Hill, NC

Abstract: In the proposed study, the frontal asymmetries of infants from normal control families are discussed. The age groups of participants are 2 weeks old, one year old and two years old. In order to understand the temporal dynamics of brain activities, high array electroencephalogram (EEG) recording technique has used while the infant quietly plays in the caregiver's lap. A short video has shown to engage 1-year old and 2-year old toddlers during the recording whereas the 2-week old infants are kept awake (eye open). First, a bandpass filter is applied to remove low frequency and high frequency components of EEG signals with a low cutoff of 1.5 Hz and high cutoff of 57 Hz. Later, the power spectrum of signals between 30-50 Hz is calculated in order to identify the frontal and occipital gamma activities. Our preliminary results showed that the frontal gamma activity is a biomarker for the early developmental differences. We are currently recruiting infants with family history of Schizophrenia. Therefore, we will be able to compare these two groups.

Title: Early depolarizing GABA controls critical period plasticity in the rat visual cortex

Authors: M. ALLEGRA[1], G. DEIDDA[2], C. CERRI[3], G. BONY[2], M. CALEO[3], *L. CANCEDDA[2]

Abstract: GABA, the main inhibitory neurotransmitter in the adult mammalian brain, plays a fundamental role for development and plasticity of the visual system. Conversely, GABA exerts depolarizing and mostly excitatory actions during early development due to high expression of the Na+/K+/Cl- cotransporter NKCC1. Interestingly, nothing is known about depolarizing GABA control of plasticity mechanisms in the visual system. Here, we interfered with depolarizing GABA action by treating rat pups with the NKCC1 inhibitor bumetanide or vehicle from P3 to P8 and examined young adult animals at P35. We found that basic physiological parameters (visual acuity, contrast threshold and binocularity) developed normally. However, differently from in control animals, the critical period for ocular dominance plasticity was still open in bumetanide-treated animals, as shown by a persistent sensitivity to the effects of a brief monocular deprivation. Moreover, visual cortical slices from bumetanide-treated rats showed reliable LTP in response to theta-burst stimulation of the white matter. Similar results were obtained with another inhibitor of NKCC1 at perinatal ages, furosemide. As we found no difference in controls and bumetanide-treated animals in experiments of monocular deprivation and LTP at P20 (the peak of the critical period) and in adult rats at P75, we concluded that the critical period was prolonged in bumetanide-treated animals. To explain the higher level of plasticity in bumetanide-treated rats at P35, we analysed basal GABAergic transmission and the extracellular matrix, which normally limit experience-dependent plasticity in the adult. We found a reduction of both the inhibitory tone and the density of perineuronal net-surrounded cells. As Brain Derived Neurotrophic Factor (BDNF) regulates the time course of critical period plasticity in the visual system by modulating maturation of inhibitory GABAergic circuits, we analysed BDNF levels in the visual cortex. We found a significant lower expression of BDNF in bumetanide-treated animals, in agreement with the delayed closure of the critical period. These

results demonstrate that early depolarizing GABA exerts a long-lasting modulation of the level of plasticity in adulthood.

Title: Heterogeneous developmental time courses of higher visual areas in mice

Authors: I. T. SMITH, L. B. TOWNSEND, C. M. MAZZONE, *S. L. SMITH
UNC Sch. of Med., Chapel Hill, NC

Abstract: Specific visual processing deficits are observed in many developmental cognitive disorders (Grinter et al 2010; Simmons et al. 2009). For example, thresholds for global motion detection are often elevated in young children with autism spectrum disorders, despite normal performance on other visual tasks. This specificity suggests that visual processing circuitry is unequally affected. In neocortex, visual pathways diverge downstream of primary visual cortex (V1) via parallel cortico-cortical projections into multiple higher visual areas (HVA). HVAs exhibit a diverse range of selectivities to visual stimuli (Marshel et al. 2011; Andermann et al. 2011), suggesting that they may be specialized for processing different aspects of visual information. Thus, if a subset of HVAs exhibit greater sensitivities to genetic and/or environmental influences in development, this could underlie the specificity of visual defects in some developmental cognitive disorders. To investigate how HVAs are affected in developmental disorders, it is crucial to first understand how these circuitries are formed during normal development. To study the development of HVAs, we turned to the mouse visual system model. Mouse primary visual cortex (V1) is surrounded by at least nine HVAs in a compact area less than 3 mm across (Wang and Burkhalter 2007). In this study, we examined the functional development of V1 and HVAs in mice during the week following eye opening (P14 - P20). Using intrinsic signal optical imaging, we mapped cortical activation in response to a battery of visual stimuli. To locate HVAs, we mapped retinotopy using individual drifting bars. To drive activity in HVAs, gratings and random dot kinetograms were used. We found that HVAs developed heterogeneously. Lateral HVAs (areas AL and LM) developed early, exhibiting

functional responses at eye opening that strengthened over days in concert with responses in V1. By contrast, medial HVAs (areas AM and PM) developed more slowly. Responses in medial HVAs were very weak to undetectable for the first two days after eye opening, and then progressively strengthened. Due to these temporally segregated time courses, the development of medial HVAs are potentially more sensitive to visual experience than that of lateral HVAs.

Title: Global hyper-synchronous spontaneous activity in the developing optic tectum

Authors: *K. IMAIZUMI[1], J. Y. SHIH[2], H. E. FARRIS[3]
[1]LSU Sch. of Vet. Med., Baton Rouge, LA; [2]Univ. of California, San Francisco, San Francisco, CA; [3]LSUHSC, New Orleans, LA

Abstract: Correlated synchronous spontaneous activity in the developing brain carries a blueprint of neuronal circuits underlying topographic organization. To understand the development of topographic organization, thus, requires knowledge of spatio-temporal patterns of spontaneous activity. We addressed this question in the developing optic tectum of albino tadpoles, Xenopus laevis, by employing an in vivo two-photon calcium imaging technique combined with a bulk-loading cell-permeant Oregon Green BAPTA-1 AM. This technique allowed us to separately monitor spontaneous activity in the input (the neuropil consisting of ascending axons and tectal dendrites) and output (tectal cell bodies) layers of the tectum. To understand the influence of visual experience, tadpoles were separately raised in normal (visual experience) and dark (no visual experience) conditions. We found that spontaneous events in the input layer depend on the developmental stage but not visual experience, while those in the output layer depend on both developmental stage and visual experience. In the output layer of the tectum, neurons are tightly correlated with average maximum correlation coefficient of ~0.5 despite the spontaneous activity, which we refer to as hyper-synchronous spontaneous activity. Furthermore, all identified neurons and the neuropil are significantly correlated with structured temporal patterns, suggesting global synchronization. In terms of global synchronization, a large

number of neuronal pairs (83 %) show the maximum correlation coefficients at 0 s time lag, suggesting that tectal neurons receive input from a common source to generate spontaneous activity (e.g., self-generation). To understand the source of this spontaneous activity, we directly manipulated sensory input to the tectum. The optic tectum receives input from visual and mechanosensory (e.g., lateral line, somatosensory, and auditory) systems through retino-tectal and hindbrain-tectal projections, respectively. The manipulation of each sensory input alone has a small or no effect on spontaneous events. However, the manipulation of both visual and mechanosensory inputs significantly alters frequency, magnitude, and temporal patterns of spontaneous activity, while preserving weak activity. The results suggest that spontaneous activity in tectal neurons is self-generated and enhanced by a non-linear combination of visual and mechanosensory inputs. This is the first study to show global hyper-synchronous spontaneous activity enhanced by a non-linear combination of visual and mechanosensory inputs in the developing brain.

Title: Changes in white matter connectivity in the visual system of people with one eye

Authors: *K. R. KELLY[1], L. MCKETTON[2], K. A. SCHNEIDER[2], J. K. E. STEEVES[1]
[1]Psychology, [2]Biol., York Univ., Toronto, ON, Canada

Abstract: Background. The present study investigated the development of white matter connectivity in the visual pathway of adults who have had one eye surgically removed (enucleated) during infancy. Previous research in our lab has revealed decreases in cortical thickness and surface area in visual cortices of this population, as well as a decrease in lateral geniculate nucleus (LGN) volume. More interestingly, these decreases were less severe in the hemisphere ipsilateral to the remaining eye, suggesting aberrant connections are made between the remaining eye and cells associated with the removed eye. This is consistent with monkey models of enucleation showing recruitment of LGN cells contralateral to the remaining eye. It is evident that grey matter development of the visual system is atypical in this population, however the effect of enucleation on white matter connectivity in this system is unclear. Methods. A

group of adults whose eye was enucleated early in life due to retinoblastoma (cancer of the retina) were compared to binocularly intact controls. All participants were scanned using a 3T Siemens Trio MRI scanner and 32-channel head coil. Anatomical regions of interest (ROIs) for the optic nerve, optic chiasm, and LGN were created by manually tracing these areas from high-resolution T1 weighted (nerve, chiasm) and proton density weighted (LGN) images. All ROI masks were registered to diffusion tensor imaging (DTI) space to determine fractional anisotropy and mean diffusivity values, and the voxel number of optic radiations (OR) per hemisphere for each participant. Probabilistic tractography was performed using DTI information to visualize and quantify tracts throughout the visual pathway. Tractography was also performed using a separate diffusion spectrum imaging (DSI) scan which allows for visualization of crossing fibers. Results. Changes in white matter connectivity were found within the visual pathway of the monocular enucleation group compared to binocularly intact controls. Specifically, we found an increase in fibers projecting to the contralateral LGN from the remaining eye. Further, an increase in the number of ORs projecting to V1 in the hemisphere contralateral to the remaining eye was also found. Conclusions. Our data are consistent with hemisphere asymmetries in visual system grey matter following monocular enucleation. The complete disruption of half of the visual inputs from enucleation appears to promote reorganization within the visual pathway via cell recruitment by the remaining eye.

Title: Maturation of visual attention for hand advance and somatosensory attention for hand withdrawal of the reach-to-eat movement in human infants aged 6 to 12 months

Authors: *L.-A. R. SACREY, J. M. KARL, I. Q. WHISHAW
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The reach-to-eat movement is a natural act in which an object or food item is grasped and transported to the mouth and it is one of the earliest forelimb behaviors displayed by human infants. In adults, there is a tight coupling between visual attention and the advance phase of the reach-to-eat movement and somatosensory attention and the withdrawal phase of the reach-to-eat movement. The present study examined when and how this relationship between sensory attention and movement develops in infancy. In a longitudinal study, eight infants, aged six months to twelve months, and twenty adults reached for familiar inanimate objects and food items. Hand and eye movements and accuracy were measured using manual, frame-by-frame kinematic analysis. The results show that there was a gradual increase in sensory coupling of vision to hand advance and somatosensation to hand withdrawal, such that by twelve months of age, infants approximated the adult pattern. A large variability in infant performance was likely the result of the concomitant maturation of the arm, hand, and rotatory movements, the development of precision grasping, and the improving targeting accuracy both for grasping and placing the target into the mouth. The results are discussed in relation to the idea that online sensory attention and motor control for reaching develops in parallel.

Title: The role of Progranulin-a during the development of the zebrafish retina

Authors: *C. WALSH[1], L. KAKUK-ATKINS[2], P. HITCHCOCK[2]
[1]Ann Arbor, MI; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Pgrn is a secreted growth factor implicated in several processes, including embryogenesis, tumorigenesis and wound repair. In humans, autosomal dominant point mutations in the progranulin gene (PGRN) result in truncated progranulin protein and haploinsuficiency. Such mutations occur in 5-10% of individuals with Frontotemperal Lobar Degeneration (FTLD), the second most common cause of early onset dementia. Our lab recently demonstrated Pgrna expression is strongly upregulated in retinal microglia in adult zebrafish after the selective death and during stem-cell based regeneration of photoreceptors. However, the specific functions of Pgrna during developmental and regenerative neurogenesis remain

unknown.
The work presented here used expression studies and reverse genetics approaches to determine the cellular expression and function of progranulin-a (Pgrna) during embryonic retinal development in zebrafish. Pgrna protein synthesis was diminished by injecting morpholino oligonucleotides (MOs), targeting the 5'UTR or third splice site (SS). Gross eye morphology and cell specific antibody markers revealed that at 72 hours post fertilization (hpf) Pgnra knock down results in the reduction of cellular differentiation in the retina compared to control or uninjected embryos. EdU labeling of dividing cells showed that in the absence of cellular differentiation, the retina persisted as a proliferative neuroepithelium. Co-injection of pgrna morpholinos and hGRN mRNA rescued the morpholino-induced phenotype. These data suggest that for retinal progenitors Pgrna functions to govern the transition from proliferation to a differentiation, and that in the vertebrate retina microglia-derived growth factors regulate aspects of developmental neurogenesis.

Title: Maturation of intrinsic properties in the optic tectum of the Xenopus tadpole

Authors: *A. S. HAMODI, K. G. PRATT
Univ. of Wyoming, Laramie, WY

Abstract: The caudal edge of the optic tectum of the *Xenopus* tadpole consists of a proliferative zone where neural progenitor cells give rise to neurons. These immature neurons then migrate rostrally into the tectum proper where they are incorporated into the retinotectal circuit (retinal ganglion cell axons projecting directly onto tectal neurons of the optic tectum). Ongoing incorporation of immature neurons from the caudal proliferative zone into the functional retinotectal circuit creates a spatial developmental gradient in which the most immature neurons are situated in the caudal portion of the optic tectum and the most mature in the rostral portion. Many aspects of neuronal maturation have been described along this rostrocaudal (RC) axis including increasing dendritic arbor complexity, increasing frequency and amplitudes of spontaneous synaptic events, increasing AMPA:NMDA ratios, and decreasing levels of calcium-permeable AMPA receptors. Much less has been reported about how the intrinsic properties may

be changing along this RC axis. Since the way a neural circuit functions is determined by both a neuron's synaptic and intrinsic properties, and since there is much evidence that these two properties are functionally coordinated, we wondered how intrinsic properties may also be changing along the same axis. Therefore, using stage 48 tadpoles, we recorded in whole cell voltage clamp configuration from neurons residing in different parts of the tectum. So far, we identified a gradual and significant increase in both peak sodium and potassium currents along the RC axis. No significant difference in cell capacitance or input resistance was observed. Furthermore, we noticed that this location-dependent increase in intrinsic currents is correlated with an increase in the amount of synaptic input received by individual neurons. This suggests that the development of intrinsic currents could be an activity-dependent process. We begin to test this possibility by altering the amount or pattern of synaptic activity received by the tectal neurons. Preliminary data suggest that chronic visual deprivation may disrupt the normal maturational gradient of intrinsic properties.

Title: Spontaneous retinal waves propagate throughout the developing visual system *in vivo*

Authors: *J. B. ACKMAN, T. J. BURBRIDGE, M. C. CRAIR
Neurobiol, Yale Univ., NEW HAVEN, CT

Abstract: The display of patterned spontaneous activity is an emergent property of the immature nervous system that is thought to mediate synaptic competition and instruct self-organization in many developing neural circuits. In the visual system, isolated preparations of developing retina exhibit propagating waves of electrical activity among neighboring retinal ganglion cells, termed 'retinal waves'. Since retinal ganglion cells relay visual information to higher order structures in the central nervous system, retinal waves are thought to play a key role in activity-dependent

refinement of topographic neural maps in the superior colliculus, lateral geniculate nucleus, and visual cortex. However, the role of retinal waves in neural circuit development remains controversial, in part because their existence has never been demonstrated in vivo. Here we use optical methods to demonstrate in live neonatal mice that waves of spontaneous retinal activity are present and propagate throughout the entire visual system before eye opening. This patterned activity encompassed the visual field, preferentially initiated in the binocular retina, and exhibited spatiotemporal correlations between the two hemispheres. Retinal waves were the primary source of activity in the midbrain and primary visual cortex and modulated ongoing activity in secondary visual areas. Thus, patterned activation of immature visual circuits by spontaneous retinal activity is likely to play an instructive role for intra- and inter- hemispheric circuit refinement across multiple visual areas.

Abstract: Although the parallel visual pathways are a fundamental basis of visual processing, our knowledge of their molecular properties is still limited. Here we uncovered the first parvocellular-specific molecule using the dorsal lateral geniculate nucleus (dLGN) of higher mammals. We found that FoxP2 transcription factor was specifically expressed in X cells of the adult ferret dLGN. Interestingly, FoxP2 was also specifically expressed in parvocellular layers 3-6 of the adult monkey dLGN, providing new evidence for a homology between X cells in the ferret dLGN and parvocellular cells in the monkey dLGN. Furthermore, this expression pattern was established as early as gestation day 140 in the embryonic monkey dLGN, suggesting that parvocellular specification has already occurred when the cytoarchitectonic LGN layers are formed. Our results should help in gaining a fundamental understanding of the development, evolution and function of the parallel visual pathways, which are especially prominent in higher mammals.

Title: Acceleration of visual acuity induced by EE is precociously primed by early increase of IGF-1 levels in the visual cortex

Authors: L. BARONCELLI[1], *M. CENNI[1], S. LANDI[2], G. DEIDDA[3], R. NARDUCCI[4], L. CANCEDDA[3], N. BERARDI[4,1], L. MAFFEI[1,2]
[1]Inst. of Neurosci CNR, Pisa, Italy; [2]Scuola Normale Superiore, Pisa, Italy; [3]IIT, Genova, Italy; [4]Dept. Psychology, Florence Univ., Florence, Italy

Abstract: Continuous exposure to enriched environment (EE) from birth to post-weaning determines a marked acceleration of visual system development both at retinal and cortical levels. Insulin-like growth factor-1 (IGF-1) is crucial in mediating EE effects on visual acuity development. Indeed, in the visual cortex, IGF-1 levels are increased by EE at P18, and post-

weaning administration of IGF-1 mimics, while post-weaning block of IGF-1 action blocks, EE effects. Interestingly, we have recently found that also limited exposure to EE in a pre-weaning period (up to P12), accelerates the much later occurring process of visual acuity development. This suggests that factors affected by EE during the first 10 days of life may be sufficient to trigger visual cortical maturation. As IGF-1 is a crucial mediator of pre-weaning EE effects on retinal development, here we explored the possible involvement of IGF-1 in mediating the effects of pre-weaning EE on visual cortical maturation.
We found that IGF-1 levels increased in the visual cortex of EE rats as early as P6. Then, we investigated whether this precocious expression of IGF-1 was a first crucial event to set in motion the process leading to a faster development of visual acuity. For this purpose, we assessed whether cortical infusions of IGF-1 by intraventricular (i.v.) injections in non EE rats from P1 to P7, was sufficient to mimic EE effects on visual acuity development, and whether blocking intracortical IGF-1 action in EE rats by means of i.v. injections of IGF-1 antagonist JB1 blocked EE effects. We found that visual acuity of non EE rats treated with IGF-1 was higher than in control rats and similar to that of rats exposed to pre-weaning EE; conversely, EE rats treated with JB1 showed visual acuity comparable to that of non EE rats.
Altogether, these results suggest that the acceleration of visual-acuity development induced by pre-weaning EE is mediated by early increase of IGF-1 levels in the visual cortex.
Moreover, to understand the mechanisms of action of this priming effect of early IGF-1 cortical levels on visual acuity development, we are currently assessing the developmental expression of chloride transporters in the visual cortex of IGF-1-treated rats. Preliminary results indicate that IGF-1 treatment accelerates the developmental decrease of NKCC1.

Title: *In vivo* examination of retinal waves and visual map development in β2 nicotinic acetylcholine receptor whole animal and conditional deletion knockout mice

Authors: *T. J. BURBRIDGE, H. XU, J. B. ACKMAN, M. C. CRAIR
Neurosci., Yale Univ., New Haven, CT

Abstract: The topographic and eye-specific organization of the mouse visual system, long a model for developmental circuit refinement, is largely organized before eye-opening and true sensory experience, but it is also known to be dependent on activity. Retinal waves, a spontaneous, patterned bursting activity studied ex vivo in dissected retinas, have provided the best guess as to the source of visual circuit-informing activity for the past twenty years, but both their in vivo existence and relative importance have been questioned. One source of this confusion stems from conflicting reports of the most widely utilized model of disrupted waves, deletion or mutation of the β2 subunit of the nicotinic acetylcholine receptor (β2-nAChR). While some in vitro reports have demonstrated a complete lack of correlated bursting retinal activity in these knockouts, others have found either more frequent retinal waves or no waves and sparse bursting in small subsets of retinal ganglion cells. We therefore developed a technique to examine and characterize spontaneous retinal activity before eye opening in awake animals in vivo through pre- and postsynaptic calcium imaging in the superior colliculus. From these experiments, we find that retinal waves do exist in vivo in β2-nAChR knockout mice, but their frequency, speed, amplitude, and direction of propagation are dramatically disrupted. Moreover, the effects of β2-nAChR knockout on retinal waves are greatest when retinofugal circuit refinement is most pronounced. Using Cre/loxP conditional knockouts, we further observed that deletion of β2-nAChRs in the retina alone was sufficient to alter spontaneous retinal activity and visual map development, while deletion of β2-nAChRs from the midbrain had no effect on retinal waves or visual circuit anatomy. These experiments thus verify the existence of altered waves in whole animal β2-nAChR knockout mice, demonstrate a pronounced developmental effect of β2-nAChR deletion on retinal wave properties, and confirm through within-animal controls in conditional mutants the hypothesis that retinal wave disruption leads directly to altered visual circuit development.

Title: Molecular basis for the development of ocular dominance patterns

Authors: *Y. WEI, A. KOULAKOV
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Neurons in the primary visual cortex of the cat and monkey form regions that are dominated by either the right or left eye. The layout of these regions is referred to as the ocular dominance pattern (ODP). The mechanism of the formation of these patterns is not fully understood. Here we propose a mechanism for the simultaneous formation of ODPs and topographic maps that is based on the interplay between the gradients of molecular labels and activity-dependent
synaptic plasticity. We propose that the segregation of geniculate inputs dominated by either eye is controlled by two competing factors. Activity-dependent synaptic plasticity tends to segregate inputs dominated by different eyes due to weaker interocular than intraocular correlations in the patterned electric activity. Molecular gradients of topographic labels, such as Eph receptors and ephrins, on the contrary, restrict the degree of such segregation. To test this mechanism, we study a computational model in which activity-dependent and activity-independent factors are combined. We make several observations about the model that make the proposed mechanism plausible. First, we show that the periodicity of ODP can vary in a wide range in this model, even within the same map. Steeper molecular gradients yield narrower ocular dominance columns, while stronger effects of correlated activity within the critical period produce wider columns. The periodicity of ODP can therefore be determined genetically, through the distribution of molecular labels in the cortex. Second, we show that monocular eye occlusion can lead to the decrease in the number of neurons dominated by one of the eyes. Third, we show that an increase/decrease in the intraocular correlations leads to the increase/decrease in the number of binocular neurons. Fourth, overall strengthening of the effects of correlated activity can lead to pattern's desegregation. Fifth, occlusion of one of the eyes may lead to the induction of ODP in the case when the ODP is not formed. Sixth, in the model, the topographic maps experience discontinuities on the interfaces between two columns of observed magnitude. Finally, we demonstrate how the direction of the molecular gradients in 2D can affect local orientation of ODP. The latter observation suggests that molecular labels may play an instructive role in the formation of ocular dominance maps.

Title: Zif268 expression in adult visual cortex uncovers perceptual learning potential in cats regardless of early visual experience

Authors: *M. ZAPASNIK[1], K. LASKOWSKA - MACIOS[1,2], T.-T. HU[2], M. KOSSUT[1], L. ARCKENS[2], K. BURNAT[1]
[1]Nencki Inst. of Exptl. Biol., Warsaw, Poland; [2]RG of Neuroplasticity and Neuroproteomics, KU Leuven, Leuven, Belgium

Abstract: Visual input during early life is crucial to establish correct vision. We analyzed the impact of early binocular pattern deprivation (BD) on motion perception. BD reduces retinal illumination and interferes with the OFF pathway development (Burnat et al., 2012). At the end of a 2-year period of behavioral motion perception training, interaction of the ON and OFF pathways was tested using a global motion task designed by Edwards and Badcock (1994). Afterwards, to test whether different behavioral outcomes of early BD are reflected in distinct cortical circuit activity, the expression profile of the activity reporter gene zif268 in the visual cortical areas 17, 19, OFF-driven PMLS and multimodal area 7 was measured. Adult BD cats deprived from eye opening for the first 2 or 4 months of life (2BD and 4BD), or for 2 months after 2 months of normal vision (2N2BD) were tested. Normal cats were raised in a normal visual environment. After completing the training cats were exposed to overnight darkness prior to 1-hour light stimulation and then sacrificed. In situ hybridization was applied using an oligonucleotide probe complementary to the nucleotides encoding amino acids 2-16 of the rat zif268 gene. Analysis of visual areas present on sections from Horsley-Clark levels A.5-A.7 was performed. Extraction of the OFF-driven global motion signal was only impaired in the 2N2BD group. As compared to the normal group, the 2BD and 4BD cats performed equally well. Nevertheless, the zif268 signal was elevated in areas PMLS, 17 and 19 in the 2BD and 4BD groups as compared to normal cats, whereas the poorly performing 2N2BD cats exhibited normal zif268 levels. We therefore suggest that the increased zif268 levels in the 2BD and 4BD cats reflect a compensation mechanism allowing the use of a different cortical circuit to perform in the global motion task. No differences in the zif268 signal between any of the BD and normal groups were found in multimodal area 7. As expected, BD altered cortical activity in motion-sensitive OFF-driven PMLS area - the 2BD and 4BD groups had significantly higher zif268 levels in the PMLS than normal cats.

Title: Interleukin-4 intravitreous injection disrupts retinotectal topography in rodents

Authors: *P. CAMPELLO-COSTA, V. G. GOULART, G. D. MENEZES, A. C. FARIA-MELIBEU, C. A. SERFATY
Neurobio., Federal Fluminense Univ., Niterói, Brazil

Abstract: The superior colliculus (SC) is a major subcortical visual center in mammals, receiving afferents from retinal ganglion cells, which establish synaptic contacts in an orderly fashion on target. The visual system undergoes an extensive structural and functional adaptation by environment modification. The main plasticity in the SC occurs during the critical period of development which corresponds to the first two/three post-natal weeks. Interleukin-4 is an anti-inflammatory cytokine that plays a role in immune and nervous systems. In the nervous system, it has been related to hippocampal neuronal survival and differentiation and retinal cells proliferation as well. In retina, IL-4 receptor (IL-4R) was identified both in photoreceptors and Müller cells process. The aim of this study was to observe the in vivo effect of IL-4 in the retinofugal pathway. Furthermore, we are looking for the IL-4R- related signaling pathways. Lister Hooded rats were injected with IL-4 or PBS (control) in the right eye at post natal day 10 (PND 10). In PND 14 the animals were injected with HRP, a neuronal marker, in the left eye. Afterwards, animals were perfused and processed to HRP histochemistry to reveal the distribution pattern of retinal axons in the SC. Alternatively, animals were processed for immunofluorescence or western blotting analysis to verified p-ERK and p-AKT content in the retina. Quantitative analysis was performed using Scion Image and Prism software. All animal use procedures were approved by the local animal care committee (CEPA-UFF) under protocol number 129/09. Our results show that animals treated with intraocular injection of PBS show a normal distribution pattern of retinotectal afferent, characterized by the presence of fibers and

terminal fields defined in clusters in the ventral and anterior region of SC. On the other hand, animals submitted to IL-4 in vivo treatment at PND10 presents an increase in retinotectal arbors, with many fibers emerging to anomalous regions of the superior colliculus. Moreover, IL-4 treatment leads to an increase in pERK content in the retina compared to PBS, control group. There was no significant difference in the content of pAKT between groups. Our results show that intravitreous treatment with IL-4 induces an increase in pERK expression in the retina and a disruption in the uncrossed retinotectal pathway of the opposite eye. Altogether, this data suggest that interleukin-4 induces a change in intra-retinal electrical activity and the consequent weakening of the contralateral retinal projections which may be contributing to the sprouting of ipsilateral retinal connections of the intact eye.

Title: Intracellular mechanisms of DSCAM and DSCAML1 during retinal development

Authors: *A. M. GARRETT[1], A. L. D. TADENEV[1], P. G. FUERST[1,2], R. W. BURGESS[1]
[1]The Jackson Lab., Bar Harbor, ME; [2]Biol. Sci., Univ. of Idaho, Moscow, ID

Abstract: Understanding how precise neural networks form is a major goal of developmental neurobiology and will provide important insights into human disease. Retinal circuits are relatively well understood with well-defined members and organization; thus the retina is a valuable model for investigating the processes and molecules that underlie neural network formation. The retina contains five major cell types, each of which can be further divided into subtypes. The cells of each subtype are spaced non-randomly to form intermingled mosaics such that each subtype is represented across the entire retina. The Ig superfamily members Down syndrome cell adhesion molecule (DSCAM) and Dscam-Like1 (DSCAML1) are expressed in non-overlapping subtypes. In mice mutant for either of these molecules, dendrites fail to form orderly, overlapping arbors, but rather fasciculate, pulling the cell bodies of other cells of the same subtype (homotypic) into clumps. Fasciculation occurs specifically among homotypic cells, not between different subtypes, and prevention of fasciculation requires homophilic DSCAM

interaction. Our working hypothesis is that DSCAM and DSCAML1 mask a cell subtype specific adhesive code. In addition to the fascicles and clumps, synapses in the mouse mutant retinas fail to mature properly. Presumably, both functions of self-avoidance to mask adhesion and contributing to synaptic structure involve interactions with the intracellular domain of DSCAM. While DSCAMs are clearly important for normal neural development, little is known about the intracellular mechanisms downstream of DSCAM. The C-termini of DSCAM and DSCAML1 are both comprised of PDZ interacting motifs, which bind specifically to the PDZ domain proteins MAGI-2 and -3 (membrane-associated guanylate kinase with inverted domain structure). DSCAM also interacts directly with the serine-threonine kinase Pak1 (p21-activated kinase 1), activating the kinase. The functional significance of these interactions in retinal development is unknown.
We generated knock in mice in which the PDZ-interacting domains of DSCAM and DSCAML1 were replaced with epitope tags. We are using these mice to ask which aspects of DSCAM and DSCAML1 function depend on their interaction with MAGI proteins and other PDZ-domain containing molecules. Using primary retinal ganglion cells, we have found that neurons mutant for DSCAM display increased self-crossings *in vitro*. We are using this system to investigate the intracellular mechanisms, including PAK1 and PDZ-domain proteins, to DSCAM-mediated self-avoidance. Together, our results will further our understanding of the mechanism of DSCAM function.

Title: Identification of three genomic loci that control AII amacrine cell number in the mouse retina

Authors: *P. W. KEELEY[1,2], I. E. WHITNEY[1,2], S. A. LEONG[3], B. E. REESE[3,2]
[1]Molecular, Cellular, and Developmental Biol., [2]Neurosci. Res. Inst., [3]Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: The establishment of neuronal populations requires specific patterns of gene expression that control different aspects of development including cellular production, differentiation, and survival. Natural variations in cell number exist across individuals, suggesting the presence of polymorphisms in the genes that control these processes. By identifying such polymorphic genes, we may gain insight into the molecular mechanisms underlying these developmental events.
In this study, we utilized recombinant inbred (RI) mice to determine the genomic loci that determine the size of the AII amacrine cell (AC) population in the mouse retina. A total of 129 mice were analyzed, with a minimum of 3 mice per strain, including the A/J (A) and C57BL/6J (B6) parental strains, and the 26 RI strains derived from them (AxB/BxA RI strain set). Each wholemounted retina was immunostained using antibodies to Prox1, and the total number of AII ACs was estimated by sampling Prox1+ cells in four quadrants across the amacrine cell layer. QTL mapping was performed using GeneNetwork (www.genenetwork.org).
While there was only a slight difference in the total number of AII ACs between the parental strains (A: 64,777 cells, B6: 69,223 cells), there was conspicuous and graded variability between the lowest and highest RI strains (BxA26: 57,141 cells, BxA2: 86,557 cells). Despite this large variability in total number, there was only slight variation within any strain as the average CoV was 0.05 for all strains, while the heritability (h^2) for this trait was estimated to be 0.74, indicating nearly three-quarters of the variation can be accounted for by an effect of strain. Because the number of AII ACs for each parental strain fell within middle of this range for the RI strains, multiple polymorphic genes must exist where the variants in a given genotype work in opposing directions. This was confirmed, as we mapped two suggestive QTLs, one on the proximal end of Chromosome (Chr) 11, where B6 alleles increased trait values by 13,252 cells, and another on the proximal end of Chr 19, where A alleles increased trait values by 13,696 cells. Composite interval mapping was conducted to control for each of these primary QTLs, which identified a third QTL on Chr 9, where A alleles increased trait values by 11,140 cells. Using chromosome substitution mice in which the A haplotype for one chromosome has been introgressed upon an otherwise B6 background, we have validated the QTLs on Chr 9 and 19, showing significant increases in the number of AII ACs (increases of 8,728 and 9,862 cells, respectively). Future work will interrogate these loci for candidate genes that contribute to the establishment of AII AC number.

Title: Optical imaging of spontaneous retinal waves with genetically encoded calcium and glutamate indicators

Authors: *M. YE[1], B. G. BORGHUIS[1], R. DUVOISIN[2], L. L. LOOGER[3], Z. J. ZHOU[1]
[1]Ophthalmology and Visual Sci., Yale Univ., New Haven, CT; [2]Dept. of Physiol. and Pharmacol., Oregon Hlth. & Sci. Univ., Portland, OR; [3]Janelia Farm Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Spontaneous retinal waves play an important role in visual system development. While the mechanism of acetylcholine-mediated retinal waves (stage II waves) has been extensively studied, the mechanism of glutamatergic retinal waves (stage III waves) remains unclear. Here we report the use of a combination of two-photon imaging of genetically encoded fluorescent proteins and electrophysiological recordings to investigate the properties of stage III wave propagation in the postnatal mouse retina. The fluorescent Ca2+ indicator GCaMP3 and the glutamate sensing protein GluSnFR were expressed in specific types of retinal cells, including On and Off bipolar cells (BCs), On and Off starburst amacrine cells (SACs), Muller cells, and ganglion cells (RGCs), following in vivo electroporation and/or viral infection of respective DNAs. Under two-photon imaging, rhythmic Ca2+ activities, with cell type-specific spatiotemporal characteristics, were recorded from BCs, SACs and RGCs during spontaneous retinal waves. BCs displayed rhythmic Ca2+ activities in the axon terminals, but not in the somata, whereas SACs and RGCs showed correlated Ca activities in both dendrites and somata. Patch-clamp recordings also detected rhythmic current inputs to BCs, SACs, RGCs, and Muller cells in the wholemount retina and revealed different kinetic properties in different cell types. Pharmacological blockade of ionotropic GABA and glycine receptors enhanced excitatory current inputs to these cells, which could, in turn, be blocked by ionotropic glutamate receptor antagonists CNQX and CPP, demonstrating a glutamate input to these cells during stage III waves. The rhythmic release of glutamate during stage III waves was further characterized by imaging the spatiotemporal properties of extracellular glutamate with GluSnFR expressed in various cell types and retinal layers. Our results show that fluorescent imaging of genetically encoded Ca2+ and glutamate sensors in specific retinal cell types, together with targeted patch-clamp recording, provides an effective approach to understanding the mechanism of stage III retinal waves.

Title: Epha/ephrina signaling and retinal spontaneous activity control sequential refinement steps during the formation of topographic maps

Authors: *I. M. BENJUMEDA
Inst. De Neurociencias De Alicante, Alicante, Spain

Abstract: Prior to the onset of sensory experience, both molecular guidance factors and spontaneous activity have been shown to play fundamental roles in the development of neural circuits and topographic maps. The relative contribution of these two mechanisms, however, is still a matter of significant debate. In particular, whether or not the presence of patterned spontaneous activity is required to activate the repulsive response of retinal axons to caudal collicular areas remains uncertain. By manipulating retinal EphA levels and blocking spontaneous activity in mouse retinal ganglion cells, we demonstrate that neural activity is not necessary to activate the EphA/ephrinA-mediated repulsive response of retinal axons during topographic map formation in the visual targets. Together, these results demonstrate that, in vivo EphA/ephrinA signaling determines the location of the axonal termination zone independently of the presence of retinal spontaneous activity and that activity is subsequently needed for proper terminal arborization.

Abstract: There are over 200,000 peripheral nerve repair surgeries performed each year in the United States, and the current gold standard for bridging nerve gaps is the autologous nerve grafts. Synthetic nerve guidance conduits avoid the donor site morbidity of the autologous graft, yet have limited efficacy, especially over longer gaps of 15 mm or more. Incorporating aligned electrospun nanofibers into the conduits has been shown to improve nerve regeneration in a rat sciatic nerve model. Many properties of electrospun nanofibers have been shown to significantly influence axonal outgrowth and migration of Schwann cells. However, the optimal fiber properties have yet to be determined to maximize regeneration outcomes. This study aims to identify ideal configurations through in vitro analysis of cell response to polycaprolactone (PCL)-gelatin nanofibers. Fiber properties analyzed include the nanofiber alignment (random versus aligned), average diameter (300 nm to 1.6 μm), fiber composition and degradation rate (PCL/gelatin ratio ranging from 0 to 100% PCL), fiber density, and fiber-conduit configuration. Primary rat Schwann cells and dorsal root ganglion explants are cultured on nanofibers both in 2D coverslips and 3D conduits to monitor cell adhesion, proliferation, migration rate, and maturation state. The cell response to the nanofibers is analyzed via fluorescence imaging and live-cell imaging. The Schwann cell maturation state is monitored by PCR and co-culture myelination assay. This study helps describe the ideal nanofiber properties to be incorporated into nerve guidance conduits to maximize functional regeneration.

Sch. of Med. and Dent. sciences, Niigata, Japan

Abstract: [Introduction] Peripheral nerve injury sometimes induces neuroma formation at the injury site.Inferior alveolar nerve (IAN) is often damaged
by dental treatments, resulting in painful symptoms. Antagonizing neurotrophin has been reported toreduce neuroma formation and neuropathic pain without damaging the transecting neurons following peripheral nerve injury, indicating the possibility that inhibition of BDNF at the injury site can repress neuroma formation. The present study aimed to examine the effects of a local application of antibody to BDNF (anti-BDNF) at the injury site on nerve regeneration and neuroma formation in a rat experimental model with IAN transection.
[Materials and Methods] A total of 22 S-D rats were used. Under general anesthesia, mandible canal at the right side was opened, and the IAN was transected. For observation of histopathological change and nerve regeneration, the animals were sacrificed at appointed time depending
on timing after the transection of IAN; postoperative (PO) 1 week (n= 2), PO 2 weeks (n=4), and PO 3 weeks (n= 8). Furthermore, the IAN transection sites (n=5) were applied with anti-BDNF (1 μg/μl) when the
IAN was cut**.** The animals with physiological saline were treated as a control (n=3). These tissue sections were processed for either AZAN staining or immunohistochemistry for protein gene product 9.5 (PGP 9.5).
[Results] An apparent morphological change was found on the proximal nerve bundles at PO 1 week; the injury site showed enlarge with a remarkable high amount of collagen fibers, indicating the neuroma formation. This neuroma became more enlarge, reached a higher level at PO 2 weeks, and remained in the almost the same volume thereafter.In experimental animals with local application of anti-BDNF, injured nerve bundles with PGP9.5 immunoreaction showed continuity with a little shrinkage. No accumulation of collagen fibers existed at the injury site in the animals treated with anti-BDNF. On the other hand, the control animals exhibited the disrupted and discontinuous IAN.
[Conclusion] IAN transection induced the formation of neuroma containing an accumulation of collagen fibers at injury site, which was inhibited by a local administration of anti-BDNF, suggesting that a local application of anti-BDNF is effective for prevention of neuroma formation in a case of peripheral nerve injury.

Title: AlphaB-crystallin knockout mice display decreased functional recovery following sciatic nerve injury.

Authors: *E.-M. F. LIM[1], S. T. NAKANISHI[2], R. KUMAR[2], P. WHELAN[3], J. BIERNASKIE[3], S. S. OUSMAN[4]
[1]Neurosci., Univ. of Calgary, Calgary, Canada; [2]Neurosci., [3]Comparative Biol. and Exptl. Med., [4]Clin. Neurosciences, Univ. of Calgary, Calgary, AB, Canada

Abstract: Partial or incomplete regeneration of peripheral nerves and the associated poor functional recovery in humans is attributed in part to an inability of Schwann cells (SCs) to maintain a supportive environment for regrowth. SCs play an important role in regeneration: they promote macrophage infiltration to clear debris, serve as scaffolds for regenerating axons, create a permissive environment by secreting neurotrophic factors, and ensheath and remyelinate regenerating axons. AlphaB-crystallin (αBC) is a small heat shock protein expressed in both mature myelinating and non-myelinating SCs. αBC has been shown to have chaperone properties, promote cell survival, prevent neurotoxicity, and suppress inflammation. We investigated whether αBC promoted SC proliferation, survival, myelination and/or neurotrophic factor secretion during sciatic nerve regeneration. The right sciatic nerve of 8-12 week old female 129S6 wild-type (WT) and αBC null mice (αBC-/-) was crushed at mid-thigh and left to recover for 28 days post-surgery. To assess for functional recovery, the DigiGait system (Mouse,

Inc.) was used to measure multiple gait parameters including swing duration, braking duration, propulsion duration, stance width, stance width variation, stance duration and paw area in naïve animals and at 28 days after injury. Motor nerve conduction velocities were also measured. No significant difference for all gait parameters was observed between WT and αBC-/- mice before injury. However, αBC-/- mice displayed gait abnormalities in all measured gait parameters that were indicative of pain sensitivity, abnormal mobility, decrease in strength and decrease in stability. In addition, there was no significant difference in the motor nerve conduction velocity between WT and αBC-/- mice before injury. Of interest however, the conduction velocity in αBC-/- mice was significantly slower compared to WT mice at 28 days post-crush. Altogether, these results demonstrate impaired functional recovery following peripheral nerve injury in αBC-/- mice following sciatic nerve crush. We are currently investigating the molecular mechanisms underlying the motor and behavioural deficits in αBC-/- mice. These findings aim to develop a greater understanding of the molecular signals that assist in SC biology and have implications for understanding disease mechanisms in inherited and acquired neuropathies, as well as provide potential ideas for therapeutic approaches to enhance peripheral nerve regeneration.

Abstract: Traumatic injury to the peripheral nervous system causing large localized nerve lesions can result in significant loss of nerve function without medical intervention. We are focusing on recapitulating the extracellular environment of naturally-regenerating nerves using hydrogel-based methods to provide localized and controlled presentation of neurotrophic cues to enhance peripheral nerve regeneration across large lesion gaps. This study aims to elucidate the importance of various neurotrophic factor (NF) gradient characteristics and presentation modalities (bound vs. diffusible) to directed axonal regrowth and Schwann cell migration using a highly-controllable hydrogel-based gradient generation method in combination with in vitro live-cell imaging platforms. By using a surface tension-driven microfluidics platform, we have generated multi-centimeter NF gradients with controlled gradient steepness, length, and concentration range. Through incorporation of immobilized heparin, we can also provide variable NF release kinetics and tunable NF presentation. The gradient hydrogels can then be incorporated into a live-cell imaging system to track and analyze the migration and outgrowth of dorsal root ganglion cells and Schwann cells; analysis using this system is ongoing. Combining a controllable NF gradient generation platform with a programmable analysis system will create a powerful tool for optimizing NF gradients for nerve regeneration applications and will further our understanding of the mechanisms underlying NF gradient-based nerve regeneration.

Title: A two-compartment organotypic model of mammalian peripheral nerve repair

Authors: *R. SIDDIQUE[1], A. VYAS[2], N. V. THAKOR[1], T. M. BRUSHART[2]
[1]Dept. of Biomed. Engin., [2]Dept. of Orthopaedic Surgery, Johns Hopkins Univ., Baltimore, MD

Abstract: Several growth factors are upregulated by Schwann cells soon after they are denervated. The role played by these factors in promoting the regeneration of adult motor neurons is poorly understood, however, because of the difficulties encountered in modeling this complex system. An experimental model is thus needed that both reproduces the complex three-

dimensional environment of peripheral nerve and facilitates control of the regeneration environment. As a first step in addressing this need, our lab developed an *in vitro* organotypic co-culture model of adult mammalian nerve repair (Vyas et al., 2009). Spinal cord sections from mice that express YFP in their motor neurons were co-cultured with segments of peripheral nerve. Once the nerve was populated with fluorescent motor axons, it was transected and joined to a nerve graft that it could then reinnervate. This system accurately models nerve repair, but cannot isolate the repair environment from that of parent motor neurons. We now describe a two-compartment model that provides this isolation. A PDMS base is divided into two fluidically isolated compartments that are separated by a central bridge. A Transwell™ membrane that rests on the bridge is transected between the compartments, and a peripheral nerve segment conveys axons from the motor neuron compartment to the experimental compartment. We have confirmed fluidic isolation of the compartments for 3 weeks, excellent axonal growth across the bridge, and robust reinnervation of nerve grafts in the experimental compartment. With this system, the regeneration environment can be manipulated by enhancing or reducing the concentration of specific growth factors without influencing parent motoneurons. The growth of regenerating axons can be monitored in real time, allowing a new level of precision in studying axon regeneration.

Title: RNA-binding protein ZBP1 associates with beta-actin and GAP-43 mRNAs with different affinities for axonal localization

Authors: *H. KIM[1], P. KIM[1], N. I. PERRONE-BIZZOZERO[2], J. L. TWISS[3], S. YOO[1]
[1]Nemours/A.I.duPont Hosp. for Children, Wilmington, DE; [2]Univ. of New Maxico, Albuquerque, NM; [3]Drexel Univ., Philadelphia, PA

Abstract: Proper mRNA transport and local protein synthesis are crucial not only during the development of the nervous system, but also for regeneration after injury. Numerous studies

have shown that targeting mRNAs to the distal processes of neurons is driven by localization signal(s), most often in the 3' untranslated regions (UTRs) of the mRNAs, and RNA-binding proteins (RBPs) that are important for RNA localization and translational regulation. 40 nucleotides in GAP-43 mRNA's 3'UTR (including the HuD binding site) are both necessary and sufficient for its axonal transport. GAP-43 and β-actin mRNAs compete for binding to ZBP1 for axonal localization (Donnelly et al., 2011). Interestingly, ZBP1 and HuD were previously shown to interact within a ribonucleoprotein (RNP) complex associated with tau mRNA (Atlas et al., 2004). Based on these observations, we asked how these HuD and ZBP1 interact to form a RNP complex containing cognate mRNAs. We transiently transfected F11 cells, a hybridoma of embryonic rat DRG neurons and mouse neuroblastoma, with Flag-tagged ZBP1 and Myc-tagged HuD. RNA-immunoprecipitation (RIP) experiments using the specific anti-Flag or -Myc antibodies demonstrate that HuD and ZBP1 co-immunoprecipitate in an RNA- dependent fashion. Both β-actin and GAP-43 mRNAs are present in the immunoprecipitates. We then determined the relative binding affinity of β-actin and GAP-43 mRNAs for binding to ZBP1 using quantitative RT-PCR analysis. Results show that although ZBP1 interacts specifically with both β-actin and GAP-43 mRNAs; this RNA-binding protein shows a higher affinity for β-actin than for GAP-43 mRNA. *In vitro* binding assays with recombinant ZBP1 and HuD proteins and qPCR analyses were used to determine if ZBP1 and HuD interact directly with the mRNAs or require additional protein binding partners. These data confirmed that ZBP1 binds to both β-actin and GAP-43 mRNAs but shows different affinities for these transcripts.

Title: Tissue engineered nerve constructs for repair of peripheral nerve injury in swine.

Authors: M. I. EZRA, J. A. WOLF, K. D. BROWNE, *D. H. SMITH
Div. Neurosurg., Univ. of Pennsylvania/Penn Ctr. For Brain Injury and Repair, PHILADELPHIA, PA

Abstract: Peripheral nerve injuries present a serious medical concern, constituting approximately 2.8 % of all trauma cases in the US, and approximately 100,000 neurosurgical procedures in the US and Europe annually. Although peripheral nerves have the ability to regenerate on their own, current techniques used to repair peripheral nerve damage do not sufficiently restore sensory and motor function, as axons are slow to extend across the injury gap and make reconnections on the distal end. The resulting limited functional recovery is often associated with inadequate muscle strength, allodynia, and an overall lower quality of life for the patient. The use of a living axonal graft to bridge a nerve injury site provides axon-mediated axon guidance to regenerating axons, increasing the rate of regeneration and therefore the likelihood of functional recovery following repair.
Previously, our group has demonstrated the ability to engineer living axonal constructs *in vitro* by applying continued mechanical stretch to axons spanning two populations of embryonic rat dorsal root ganglia (DRG) neurons to repair damaged nerves in a rat model. In the current study, we aim to scale up the living nerve constructs to a larger, more clinically relevant model by using dissociated adult porcine DRGs. Here, axons are rapidly stretch grown ex vivo to a length necessary to span the nerve damage in a pig model of peripheral nerve injury. This novel method attempts to emulate neuronal growth mechanisms observed during normal development in large animals, such as the blue whale and the neck of the giraffe. For the current work, we plate dissociated DRGs from an adult pig onto 2 separate plastic membranes: one population on the stationary side and the other on the “towing” side. First, axons are allowed to grow and synapse with neurons on the other membrane for 5 days. Then, the population on the towing membrane is slowly pulled away over several days, aided by a precise computer-controlled motor system, creating long tracts of living axons. We have successfully optimized a protocol to isolate porcine DRGs, dissociate and purify the cells, and culture them under various conditions *in vitro* for greater than 7 weeks. Additionally, we have begun to culture the dissociated DRGs in our elongation systems, and experimented with stretching the axons at various rates in order to optimize overall length and health of the constructs. In the future, we aim to construct porcine axonal constructs in vitro up to 10 cm in length for use to repair defects in the porcine peroneal nerve. This approach may be used to establish or promote functional connections needed for nervous system repair that have not been achieved by other methods.

Abstract: Recently, we showed that stress and glucocorticoids (GCs) exacerbate neuropathic pain caused by injuring the peripheral branches of axons from dorsal root ganglion (DRG) neurons. Stress and GCs are known to affect neuroplasticity in the hippocampus; however, it is not known if similar effects occur in DRG neurons. Western blots revealed greater expression of glucocorticoid receptors (GR) in DRG neurons relative to other stress-responsive regions of the central nervous system, including the hippocampus. DRG neurons isolated from mice subjected to acute (60 min) restraint stress exhibited robust structural plasticity in vitro; both the length and complexity of axon growth was increased compared to neurons isolated from non-stressed mice. These effects were GC- and mTOR-dependent, as pre-treatment of mice with a glucocorticoid receptor (GR) antagonist or mTOR inhibitor (rapamycin) prevented the axon growth-promoting effects of stress on DRG neurons. To explore molecular mechanisms of GR-mediated sensory axon plasticity, regeneration-associated genes (RAGs) that potentially interact with GR were identified by *in silico* gene networking analysis, and interactions were tested using luciferase reporter assays. A constitutively active form of GR significantly increased transcription of several RAGs identified in the network analysis. A transcription factor binding site prediction program identified GR-responsive elements in the promoter regions of these same RAG genes. To test RAG upregulation in vivo, mice were subjected to acute stress followed by crush of the sciatic nerve. PCR analysis of mRNA isolated from DRG neurons confirmed that stress induced RAG expression in vivo. Overall, our experiments reveal the sensitivity of DRG neurons to stress and GCs, which may result in profound anatomical and functional consequences after injury.

Title: Sensory neurite outgrowth and guidance by electrospun fibres and microtubes *in vitro*

Authors: M. KANJE[1], A. GHASEMI AZAR[1], *F. JOHANSSON[2]
[1]Biol. Dept., [2]Lund Univ., Lund, Sweden

Abstract: We have previously shown that it is possible to orient nerve fibres by nano- and µ-sized structure alteration of surfaces[1]. Others have demonstrated that neurites can grow along electrospun polymer fibres[2].
In the present study we investigated neurite outgrowth from mouse dorsal root ganglia on electrospun µm-thick fibres made of poly L-lactic acid (PLLA) and assemblies of tubes of polystyrene with an average inner diameter in a range of 20-100 µm. The electrospun fibres were collected on coverslips. The tubes were produced by a tailor made dry spinning system. Individual tubes were assembled into bundles and the space between the tubes filled with polymethylsiloxane (PDMS). Suitably sized (a few mm long)) cross sections were then cut from the tube assemblies. In cross section, only the tube openings were thus left for possible in-growth of neurites. Excised dorsal root ganglia from adult mice were subsequently mounted in Matrigel® on top of the cut tubes or the electrospun fibres. The entire preparation was incubated in a tissue culture dish containing serum-free medium supplemented with nerve growth factor. After a few days culturing the preparations were washed, fixed and stained with antibodies to neurofilaments in order to visualize regenerating neurites.
The neurites grew and oriented along the electrospun fibres.
In the tube experiments, neurites occasionally grew into and down the holes in the tubes. However, most neurites were found on the surface of the tube assembly.

We conclude that either fibres or tubes can act as guides for neurites. The present models for neurite outgrowth are suitable for studies of neurite guidance effects of both tropic, trophic factors.

Title: Characterization of the Octopus arm morphology and its regenerative capability: Role of Acetylcholinesterase during morphological modification.

Authors: *S. FOSSATI[1], F. CARELLA[2], G. DE VICO[2], F. BENFENATI[1], L. ZULLO[1]
[1]Neurosci. and Brain Technol., Fondazione Inst. Italiano Di Tecnologia, Genova, Italy;
[2]2Federico II Univ. of Naples, Dept. of Biol. science, Naples, Italy

Abstract: The ability of regenerate whole-body structures has been long studied and still has a peculiar interest in stem cell biology for its therapeutic potential. Regeneration of arms in Cephalopods and in particular in Octopods has been the subject of several studies. The first study on the regeneration of the Octopus arm demonstrated that all regenerated tissues, with the exception of the dermal connective tissue, are produced by the pre-existing tissues of the same kind. However, the details of the regenerative process in the Octopus arm remain to be elucidated. Using Octopus vulgaris as model of regeneration, we are investigating the role of different cell types and neurotransmitters in the regenerative process. Since Octopus has a typical cholinergic innervation at the level of the arm neuromuscular system, we investigated the involvement of acetylcholinesterase (AChE) in the Octopus arm regeneration. AChE has been demonstrated to have non-cholinergic functions in various cell types and to be involved in the regulation of cell proliferation, differentiation and apoptosis. Our hypothesis is based on previous studies, which showed that in lower invertebrates and amphibians different expression levels of

AChE are associated with the regeneration phases. In order to follow cell replacement in the Octopus arm, we first assessed the expression of specific markers involved in cellular proliferation (AgNOR and PCNA). Our results showed that the activity of the enzyme AChE is related to the proliferation stage of the arm regenerative process. Interestingly AgNOR and AChE assay showed a similar trend in particular during the stages when the morphogenesis was mostly dependent upon cell proliferation. We suggest that AChE protein may have an important influence in the process of regeneration and that it could be considered as a potential target to promote or regulate the regenerative process. In order to follow the expression of the AChE gene during regeneration we are now completing the cloning of the entire gene of AChE. AChE is a molecule that evolved very early in evolution and is well conserved across species. So far we obtained a fragment of 1044 bp, corresponding to a protein of 348 aa, which has high homology with the AChEs of other animal species. Our next step is to produce a probe for in-situ experiments to detect different levels of expression of AChE in samples at various stages of regeneration. This will allow us understanding some latent basic pathways to unlock to promote regeneration.

Title: Carbon nanotubes enhance sensitivity and safety of regenerative multi electrode interfaces

Authors: A. KANNEGANTI[1], S. ANAND[1], R. GRANJA[1], E. KEEFER[2], *M. I. ROMERO-ORTEGA[1]
[1]Bioengineering Deparment, Univ. of Texas at Arlington, Arlington, TX; [2]Plexon Inc, Dallas, TX

Abstract:
Advanced robotic limbs are multi-fingered lightweight devices capable of up to 22 degrees of freedom. However, providing users with natural control and feel of such robotic limbs remains a formidable challenge. Peripheral nerves in the residual limbs of amputees, offers a readily accessible portal to the bidirectional flow of information between the nervous system of the user

(motor), and smart robotic prosthetic devices (sensory). To access such portal, several types of peripheral nerve interfaces (PNI) have been developed along a spectrum of invasiveness and sensitivity. We have reported enhanced sensitivity in single spike recordings using carbon nano tube (CNT) coated electrodes for acute brain implantation. Despite the significant advantages of increased surface area and decreased impedance by CNTs, the long-term reliability in the recording of such electrodes has not been investigated. Here, we show the long term recording of the peripheral neural activity with CNT-coated multi-electrode
arrays in rats during bipedal locomotion. We implanted adult Lewis rats with electrodeposited CNTs on 18-electrode Pt/Ir arrays placed in the regenerative path of the transected sciatic nerve, using 7 mm collagen-filled polyurethane tubes. Neural activity was recorded over time and the changes in the signal quality were quantified. Persistent single spike
activity was observed in chronic nerve implants 30 days post-implantation, and the regenerated tissue was harvested and processed for the visualization of various molecular markers, targeting the molecules associated with the tissue response to the implant. Preliminary results show comparable immune response to uncoated multi electrode implants. This study shows for the first time that CNT-coated REMIs can provide enhanced signal to noise ratio and sensitive recordings of single spike activity in regenerative peripheral neurointerfaces after long term implantation. Together, this data shows that CNT-REMI electrodes provide a sensitive interface for the chronic recording of single spike activity and the safe stimulation of regenerated axons.

Title: Adhesion molecule L1-mediated axonal myelination correlates with L1's proteolytic cleavage

Authors: *D. GUSEVA[1,2], M. SCHACHNER[2,3,4]
[1]Cell. Neurophysiol., Hannover Med. Sch., Hannover, Germany; [2]Zentrum für Molekulare Neurobiologie, Univ. Hamburg, Hamburg, Germany; [3]Keck Ctr. for Collaborative Neuroscience, Rutgers Univ., Piscataway, NJ, NJ; [4]Ctr. for Neuroscience, Shantou Univ. Med. Col., Shantou, China

Abstract: Adhesion molecules, which are involved in neurogenesis, synapse formation and myelination, are proteolytically cleaved to achieve functional activity. This posttranslational modification has become of particular interest in morphogenetic events during development of the nervous system. The adhesion molecule L1 shapes development of the nervous system and is beneficial for repair processes in the adult central nervous system of vertebrates by promoting axonal regrowth and neuronal survival. In the peripheral nervous system, L1 is up-regulated by myelination-competent Schwann cells and regenerating axons after nerve damage. L1 is a 200 to 220 kD type I transmembrane protein and consists of six immunoglobulin (Ig)-like domains followed by five fibronectin type III-like repeats and a single transmembrane region that is linked to a short cytoplasmic domain that is highly conserved among members of the L1 family. In the mouse brain, L1 protein is detectable in four distinct molecular forms with sizes of 200, 180, 140, and 80 kD. Previously it was shown that L1 is processed by ADAM10 to yield 85 and 32 kD fragments. The proprotein convertase PC5A also plays an essential role in L1 processing leading to the proteolytic 180 and 140 kD fragments. Here we show that transgenic mice overexpressing L1 under the control of the neuronally active Thy-1 promoter are not different in functional recovery compared with wild-type littermates 12 weeks after femoral nerve injury. However, remyelination in the distal stump of the injured nerve was considerably more improved in transgenic mice than in wild-type littermates. Interestingly, in L1-overexpressing mice the levels of the transmembrane 70 kD fragment of L1 are decreased in the femoral nerve after injury and in the lesion-corresponding spinal cord segments at 5 days after injury, when compared with wild-type littermates. We interpret these findings by assuming that the 70 kD fragment attenuates remyelination by allowing preferential full-length homophilic L1 trans-interactions between Schwann cells and axons, coincident with blocking sites for cleavage, thus allowing full-length L1 to signal transduce in the two interacting cell types of the peripheral nervous system. Our data suggest that L1-mediated axonal myelination requires proteolytic processing of L1 during remyelination after peripheral nerve injury.

Abstract: Robust axonal regeneration in the central nervous system remains elusive, while peripheral neurons are known to regenerate their axons after injury. Changes in gene expression, including changes in specific mRNA isoforms (PLoS One, 7(1): e30417) comprise one mechanism controlling the regeneration process. We took advantage of Next Generation Sequencing of the Transcriptome (RNA-Seq) to identify mRNA isoforms differentially expressed in the neurons of the dorsal root ganglion (DRG) after sciatic nerve crush, an injury that is known to initialize the axonal regeneration program in these neurons. The expression of different RNA species is influenced by and influences the activity of small regulatory RNAs (e.g. microRNAs). Therefore we also utilized Quantitative Real-Time PCR to explore differential expression of microRNAs in the same experimental paradigm, to reveal events regulating transcription of individual isoforms. We identified more than 2000 mRNA isoforms and more than 40 microRNAs that were differentially expressed in DRG neurons 7 days after axotomy. Among these changes were a number that have been previously described, but our approach also revealed, for the first time, differential expression on an isoform specific basis. Among the microRNAs, we observed downregulation of mir-9, a neuronal specific microRNA whose inhibition increases axon length in cortical cells (Nat Neurosci., 15: 697-699). We are currently using a bioinformatic approach to predict the interactions among these mRNAs and microRNAs, and thus to describe the regulatory network behind the transcriptional profile of regenerating DRG neurons. A High Content Analysis approach will be used to confirm in vitro the functional role of predicted network nodes in axon regeneration of peripheral and central nervous system neurons. Overall these experiments will enable us to elucidate new mechanisms behind gene expression regulation, by revealing changes in regulatory RNAs and how they regulate specific RNA isoform expression, thus furthering our understanding of the genetic mechanisms underlying the process of axon regeneration.

Title: Dose dependency of the effectiveness of galantamine to counter the neurotoxicity of the organophosphorus poison VX

Authors: E. DOWLATI[1], C. HAWKINS[1], Y. ARACAVA[1], *G. W. BASINGER, Jr.[2], E. F. R. PEREIRA[1], J. MAMCZARZ[1], E. X. ALBUQUERQUE[1]

Abstract: In recent years galantamine, a drug currently approved for treatment of Alzheimer's disease, emerged as a potential medical countermeasure against the acute and delayed toxicity induced by organophosphorus compounds (OPs), including the nerve agents soman, sarin, and VX, and a number of pesticides (PNAS103:13220, 2006; Neurotoxicology 32:785, 2011). The present study was designed to assess the immediate and delayed toxicity of the nerve agent VX and the effectiveness of a delayed post-treatment with galantamine to counter the effects of VX. The guinea pig was the animal model of choice because the sensitivity of humans and non-human primates more closely resembles that of guinea pigs than of other rodents. Here, adult male guinea pigs were injected subcutaneously with saline or VX (0.6x or 1.0xLD50). Within 1 h after the challenge with 1.0xLD50 VX, guinea pigs started to present with signs of acute intoxication, including facial twitches, chewing, and head tremors. Within 3 h, more severe signs of acute intoxication, including convulsions and respiratory distress, became readily pronounced in approximately 50% of the animals. Animals were euthanized, according to the IACUC-approved protocols, whenever signs of acute intoxication became life-threatening. By 24 h following the initial injection of 1.0xLD50 VX, 45% to 50% of the animals remained alive in the different experimental groups. At this time, galantamine (2-10 mg/kg) or saline (0.5 ml/kg) was injected intramuscularly to the animals in all test groups. Neither galantamine nor saline altered the survival outcome of the animals that had been injected 24 h earlier with VX (0.6x or 1.0xLD50) or saline. Three months later, locomotor and exploratory activities of the guinea pigs were assessed in a large open field arena. The overall locomotor activity of the VX-challenged guinea pigs was comparable to that of control (saline/saline-injected) animals. However, VX-exposed guinea pigs presented with anxiety-like behavior; the number of entries to the center zone of the arena as well as the distance traveled and the time spent in this zone were significantly lower among VX-challenged animals than among control animals. The effect of VX was dose dependent, being more pronounced at 1.0xLD50 than 0.6xLD50. Galantamine, dose dependently, countered the anxiety-like behavior triggered by exposure of the guinea pigs to VX; the most effective dose of galantamine was found to be 4 mg/kg. These results support the

contention that post-treatment with galantamine can effectively counter delayed behavioral alterations triggered by an acute exposure to the nerve agent VX.

Title: Effect of prenatal exposure to chlorpyrifos on cognitive performance of guinea pigs

Authors: L. GAVRUSHENKO, J. D. PESCRILLE, *E. F. PEREIRA, E. X. ALBUQUERQUE, J. MAMCZARZ
Div. of Translational Toxicology, Dept Epidemiol Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD

Abstract: An ever growing number of epidemiological studies have provided evidence of organophosphorus (OP) pesticide toxicity to the developing human brain. The present study was designed to test the hypothesis that changes in cognitive and non-cognitive behavior become apparent in offspring born to mothers exposed to low doses of OP pesticides, including chlorpyrifos. To this end, we used guinea pigs, a precocious rodent species that is considered the best non-primate model of human OP intoxication. Pregnant guinea pigs received one daily injection of chlorpyrifos (25 mg/kg s.c.) or peanut oil for 10 days starting on gestation day (GD) 50-53. Offspring were born on GD 65-67, weaned from mothers on postnatal day (PND) 20, and housed according to their sexes. Around PND 30 evaluation of locomotor and exploratory activity started in open field and novel object exploration tests. The overall locomotor activity of the animals was very similar across sexes and treatments. However, in the presence of a novel object, males maintained higher locomotion than females, and males that were exposed in utero to chlopyrifos spent more time close to the object than sex-matched animals that had been exposed to peanut oil. For evaluation of cognitive functions, animals were first trained to find a hidden escape platform in a fixed position in the Morris water maze (MWM) (5 days x 4 trials). After a two-day break, animals were subjected to two days of probe tests, consisting of complete removal of the escape platform, and then two days of platform relocation (4 trials with 1 hour

inter-trial-interval). In the reference memory training, males performed better than females. In addition, males and females that had been exposed in utero to chlorpyrifos did not perform as well as sex-matched guinea pigs that had been exposed to peanut oil. In the first probe test, chlorpyrifos-exposed males showed no spatial bias, whereas peanut oil-exposed males swam preferentially in the area where the escape platform used to be located. On the second probe test neither sex showed spatial bias. When subjected to training to find the escape platform in new locations, male and female guinea pigs that had been exposed in utero to chlorpyrifos were significantly impaired compared to sex-matched animals that had been exposed to peanut oil. These results demonstrate that following in utero exposure to chlorpyrifos young adult guinea pigs present with significant cognitive impairment.

Title: *In utero* chlorpyrifos exposure leads to augmented CA1 pyramidal GABAergic transmission in the adult male guinea pig

Authors: *R. D. BURKE, E. X. ALBUQUERQUE, E. F. R. PEREIRA
Div. of Translational Toxicology, Dept. of Epidemiology and Publ. Hlth., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The organophosphorus (OP) pesticide chlorpyrifos (CPF) is among the most commonly used pesticides in the US. Accounting for roughly 50% of the millions of pounds of OP pesticides used yearly, CPF is widely applied to the US food stock. Epidemiological studies report that children who are exposed *in utero* to OP pesticides, including CPF, present higher incidence of cognitive impairments, attention deficit/hyperactivity disorder, and autism spectrum disorders than non-exposed children. Cognitive impairments have also been demonstrated in rats and mice following *in utero* exposure to doses of CPF that do not induce overt maternal toxicity and significant acetylcholinesterase (AChE) inhibition. The current study was designed to test the hypothesis that *in utero* exposure of guinea pigs to CPF impairs synaptic transmission in the hippocampus, a major brain region involved in cognitive processing. Guinea pigs were the model

of choice because like primates, they are precocious. *In utero* development of the brain of guinea pigs parallels that of primates. Dunkin Hartley guinea pig dams were injected subcutaneously with CPF formulated in peanut oil (0.05 LD50, 25 mg/kg/day, 0.5 ml/kg) or peanut oil (0.5 ml/kg) once daily on days 50 to 60 of presumed gestation (GDs 50 to 60). Adult male pups were euthanized on postnatal days 60 to 72 (PNDs 60 to 72). Their hippocampi were harvested, and inhibitory (IPSC) and excitatory (EPSC) postsynaptic currents were recorded by means of the whole-cell patch-clamp technique from CA1 pyramidal cells in hippocampal slices. The internal pipette solution was such that the reversal potential of Cl^- was approximately -45 mV. Thus, IPSCs and EPSCs were isolated utilizing voltage manipulation. The frequency and transferred charge of IPSCs were significantly elevated (2.11x and 2.16x, respectively) in CPF-exposed male guinea pigs (8 animals; 1 to 3 cells per animal, 15 cells) as compared to control (6 animals, 1 to 4 cells per animal, 14 cells). Current analysis discloses no significant difference from control in EPSCs. This augmented CA1 pyramidal inhibitory tone could prove to partially underlie cognitive deficits observed in the morris water maze following *in utero* exposure of guinea pigs to CPF (Mamczarz et al, presented at current meeting).

Title: Effectiveness of galantamine and pyridostigmine to prevent the acute toxicity of the organophosphorus nerve agent sarin: Telemetric EEG recordings and Fluoro-Jade staining

Authors: *Y. ARACAVA[1], M. ADLER[3], G. KULKARNI[1], J. R. HUNT[1], E. F. R. PEREIRA[1], L. DETOLLA[2], E. X. ALBUQUERQUE[1]
[1]Div. of Translational Toxicology, Dept Epidemiol Publ. Hlth., [2]Program in Comparative Med., Univ. Maryland Sch. Med., Baltimore, MD; [3]USAMRICD, APG, MD

Abstract: The nerve agent sarin, one of the most toxic organophosphorus (OP) compounds, has been used in terrorist attacks against civilians in Japan and in the battlefield. In the event of an acute exposure to nerve agents, treatment with the muscarinic receptor antagonist atropine, the acetylcholinesterase reactivator pralidoxime, and the anticonvulsant diazepam may be necessary to prevent their acute toxicity and lethality. In 2003, the FDA approved the use of pyridostigmine bromide (PB) as pre-treatment for military personnel at risk of exposure to the nerve agent soman. In recent years, galantamine emerged as an effective medical countermeasure against OP poisoning (PNAS103:13220, 2006). Here, we compared the pre-treatment efficacy of galantamine to that of PB in protecting guinea pigs against the acute toxicity and lethality of multiple lethal doses of sarin. Guinea pigs were treated with PB (0.026 mg/kg, im) or galantamine (8-12 mg/kg, im) 30 min prior to their subcutaneous challenge with 3x or 4xLD50 sarin. One min after sarin challenge, guinea pigs were treated with atropine sulfate (0.5 mg/kg, im) and pralidoxime HCl (25 mg/kg, im). Twelve min after the injection of sarin, when motor convulsions became evident, guinea pigs were treated with diazepam (1.25 mg/kg, im). EEG activity was recorded telemetrically from these animals 2 h before and for 24 h after the sarin injection, and neurodegeneration was assessed by Fluoro Jade B (FJB) staining. Analysis of EEG recordings revealed that seizures elicited by 3xLD50 sarin subsided within an h, with no recurrence, regardless of whether the animals that had been pre-treated with galantamine or PB. However, a different profile for pretreatment efficacy emerged with 4xLD50 sarin. In animals pre-treated with 12 mg/kg galantamine, seizures induced by 4xLD50 sarin lasted less than an h; seizures recorded from PB-pretreated guinea pigs that were challenged with this dose of sarin were more severe, lasted longer, and recurred during the 24-h recording. Accordingly, FJB staining showed extensive degeneration of neurons in the piriform cortex, amygdala, and hippocampus of guinea pigs that were pre-treated with PB and challenged with 4xLD50 sarin. No FJB staining was evident 24 h after the challenge with 4xLD50 sarin in guinea pigs that had been pre-treated with galantamine or on those that were exposed to 3xLD50. In conclusion, galantamine is more effective than PB in preventing the lethality, controlling seizures, and limiting neuronal death induced by high levels of sarin. Title: Effects of an acute exposure to the organophosphorus poison VX on the pharmacokinetics of galantamine in guinea pigs

Authors: R. H. COOMBES, J. R. HUNT, Y. ARACAVA, *J. BANERJEE, E. F. R. PEREIRA, E. X. ALBUQUERQUE, W. P. FAWCETT
Div. of Translational Toxicology, Dept. of Epidemiology and Publ. heal, Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Galantamine, a reversible acetylcholinesterase (AChE) inhibitor that is currently approved for treatment of mild-to-moderate Alzheimer's disease, has emerged as an effective antidotal therapy against the acute toxicity of organophosphorus (OP) nerve agents and pesticides (Albuquerque et al., PNAS 103: 13220, 2006). In the present study, we evaluated the pharmacokinetic profile of galantamine in adult male and female guinea pigs that were injected subcutaneously with saline (0.5 ml/kg) or VX (0.6x or 1xLD50) and 24 h later treated intramuscularly with galantamine (2, 4, 8, or 10 mg/kg). Blood (0.4 ml) was collected from a jugular vein catheter into heparinized ependorf tubes before and 5, 15, 30, 60, 120, 240, 360, and 450 min after the treatment. Plasma concentrations of galantamine were determined by means of high-performance liquid chromatography as described in Albuquerque et al. (2006). At all doses tested, the pharmacokinetic profile of galantamine was not significantly different between male and female guinea pigs. For example, in saline-injected males that were post-treated with 2 mg/kg galantamine (n = 6), maximal concentration of galantamine (Cmax), time to reach Cmax (Tmax), area-under-the-curve (AUC), and half-life (t1/2) were 0.33 ± 0.06 µg/ml, 12.5 ± 5.1 min, 23.8 ± 7.54 µg/ml.min, and 51.5 ± 28.2 min, respectively. In females injected with the same dose of galantamine (n = 6), Cmax, Tmax, AUC, and t1/2 were 0.38 ± 0.03 µg/ml, 11.0 ± 2.45 min, 35.6 ± 2.82 µg/ml.min, and 75.9 ± 13.7 min, respectively. While Cmax and Tmax were not affected by the VX challenge, t1/2 and AUC were significantly different ($p < 0.01$)between control and VX-injected guinea pigs that were post-treated with 2 or 4 mg/kg galantamine. For example, in adult male guinea pigs that were challenged with 0.6xLD50 VX and 24 h later treated with 2 mg/kg galantamine, Cmax, Tmax, AUC, and t1/2 were 0.49 ± 0.15 µg/ml, 10.0 ± 5.48 min, 85.4 ± 19.0 µg/ml.min, and 174.1 ± 36.8 min, respectively. Following the challenge with 1xLD50 VX, AUC and t1/2 were further increased to approximately 190 µg/ml.min and 230 min, respectively. The finding that an acute exposure to VX increases the bioavailabilty of low doses of galantamine may be accounted for by decreased metabolism of the drug due to the hepatotoxic effects of VX.

Title: Effect of prenatal exposure to soman on cognitive performance of guinea pigs

Authors: J. PESCRILLE, L. GAVRUSHENKO, Y. ARACAVA, E. F. R. PEREIRA, E. X. ALBUQUERQUE, *J. MAMCZARZ
Dept Epidemiol Publ. Hlth., Univ. of Maryland Sch. Med., Baltimore, MD

Abstract: The sensitivity of the developing brain to organophosphorus (OP) nerve agents and the safety of antidotes to pregnant women and developing fetuses are unknown. Thus, during the 1995 terrorist attack with the nerve agent sarin in Tokyo, pregnant women who sought medical attention after presenting mild signs of OP toxicity received no therapeutic treatment (J Clin Neurosci 9:17, 2002). The urgency of studies to investigate the developmental neurotoxicity of nerve agents is underscored by the recent report of neurobehavioral teratogenicity of sarin in an avian model (Neurotoxicol Teratol 31:406, 2009). Here, we tested the hypothesis that the developing mammalian brain is exquisitely sensitive to nerve agents, including soman. We used guinea pigs because: (i) their brain development closely resembles that of humans and non-human primates, and (ii) like humans, guinea pigs have low levels of circulating carboxylesterases -enzymes that metabolically inactivate OPs. Pregnant guinea pigs were injected with soman 1xLD50 (12 ug/kg, sc) or saline (0.5 ml/kg, sc) between the shoulder blades around gestation day (GD) 50. Offspring were born at term around GD65-67, weaned from mothers on postnatal day (PND) 20, and housed according to their sexes. Evaluation of cognitive functions started around PND 30-40 in the Morris water maze (MWM). During the acquisition phase, animals were trained to find a hidden platform in a constant location in two 5-day blocks (4 trials a day) interspaced by 2-day break. Memory retention was analyzed in probe tests performed in the pool without the platform three days after finishing each training session. Guinea pigs that had been exposed in utero to soman showed significant learning impairment during the first 5-day block of the acquisition phase of the MWM task; only towards the end of the second training block, animals that had been exposed in utero to soman were able to find the

hidden platform as well as control animals. To further evaluate the nature of the learning impairment of the soman-exposed guinea pigs, all animals were trained to find a hidden platform in a MWM that was located in a testing room completely distinct from the previous one. The acquisition phase consisted of 5-day training (4 trials a day) and was followed three days later by a probe test. The learning impairment of soman-exposed guinea pigs became apparent again in the new testing room. These results demonstrate that prenatal exposure to soman trigers significant leaning impairment and that this impairment is likely due to inability of the animals to process spatial information.

Title: Cognitive impairment in adult male guinea pigs long after an acute exposure to the organophosphorus poison soman

Authors: E. F. R. PEREIRA[1], J. D. PESCRILLE[1], L. GAVRUSHENKO[1], *R. GAMMANS[2], J. MAMCZARZ[1], E. X. ALBUQUERQUE[1]
[1]Div. of Translational Toxicology, Dept. Epidemiology and Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD; [2]Countervail Corp., Charlotte, NC

Abstract: Nerve agents, including soman, are compounds chemically related to, but far more toxic than organophosphorus (OP) pesticides. It is well known that exposure to lethal doses of these compounds triggers a cholinergic syndrome that results primarily from the irreversible inhibition of acetylcholinesterase. The syndrome is characterized by excessive chewing, hypersecretions, loss of motor coordination, convulsions, and respiratory arrest. Recently we reported that cognitive impairment develops months after an acute exposure of prepubertal female guinea pigs to 1xLD50 soman (Neurotoxicology 32:785, 2011). Since there is evidence that the acute toxicity of nerve agents in guinea pigs is sex and age dependent (J Pharmacol Exp Ther 328:516, 2009), the present study was designed to determine whether the delayed neurotoxic effects of soman can also be detected in adult male guinea pigs. To this end, adult

male guinea pigs (3 months old) were injected subcutaneously with 1xLD50 soman (26.3 µg/kg) or saline (0.5 ml/kg). Four months later their cognitive performance was evaluated in the Morris water maze. Animals were trained to find a hidden platform in a constant position in two 5-day blocks (4 trials a day) interspaced by 2-day break. Memory retention was evaluated in probe tests that were performed 3 days after finishing each of the training blocks. During the first 5-day training block, soman- and saline-injected animals performed equally well in the MWM. The escape latency and the distance they travelled to reach the hidden platform were comparable between the two treatments. During the second 5-day training block, saline-injected animals continued to learn to reach the platform, as evidenced by the progressive shortening of the escape latency and distance traveled with days of training. On the other hand, learning did not progress with soman-challenged guinea pigs during the second training session. Memory retention was also impaired by soman. To further evaluate the ability of the animals to process information from spatial cues, animals were transferred to a new room, with distinct configuration, and trained in another MWM in a 4-day block (4 trials a day). Memory retention was evaluated 4 days later in a probe test. Soman-challenged guinea pigs were memory impaired when compared to control animals. Thus, exposure of adult male guinea pigs to the same dose of soman affects cognitive processing of spatial cues. This is in contrast to the procedural learning impairment that has been reported to develop months after an acute exposure of prepubertal female guinea pigs to 1xLD50 soman (Neurotoxicology 32:785, 2011).

Title: Tonically active α7 nicotinic receptors (nAChRs) regulate glutamate synaptic activity in CA3 pyramidal neurons to maintain glutamatergic input to CA1 pyramidal neurons

Authors: M. ALKONDON[1], J. BANERJEE[1], E. F. R. PEREIRA[1], *W. T. REGENOLD[2], E. X. ALBUQUERQUE[1]
[1]Div. of Translational Toxicology, Dept Epidemiology and Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD; [2]Psychiatry, Univ. of Maryland, Baltimore, MD

Abstract: Recently we reported that in the rat hippocampus glutamatergic transmission to CA1 pyramidal neurons is maintained in part by tonically active α7 nAChRs. The location of these receptors remains elusive, however. The major glutamatergic input to CA1 pyramidal neurons arise from CA3 pyramidal neurons through the Schaffer collaterals. CA3 pyramidal neurons and the mossy fibers that synapse onto these neurons are known to express α7 nAChRs. Thus, this study was designed to test the hypothesis that tonically active α7 nAChRs that contribute to the maintenance of glutamatergic synaptic inputs to CA1 pyramidal neurons are largely in the CA3 field of the hippocampus.To test this hypothesis, action potential-dependent excitatory postsynaptic currents (EPSCs) were recorded from CA1 and CA3 pyramidal neurons in rat hippocampal slices under various experimental conditions. The mean frequency of spontaneous EPSCs recorded from CA3 pyramidal neurons (0.87 ± 0.03 Hz) was found to be higher compared to that from CA1 pyramidal neurons (0.61 ± 0.03 Hz). The α7 nAChR antagonist methyllycaconitine (MLA, 10 nM) suppressed the frequency of spontaneous EPSCs by 29.4 ± 2.1% and 22.4 ± 2.3%, respectively, in CA1 and CA3 pyramidal neurons,while having no significant effect on the kinetics of the events. Surgical ablation of the CA3 region from the slices caused a 30.6 ± 4.1% and 22.2 ± 2.1% reduction in frequency and peak amplitude, respectively, of spontaneous EPSCs recorded from CA1 pyramidal neurons. Moreover, in CA3-free slices, the effectiveness of MLA (10 nM) to suppress the frequency of spontaneous EPSCs recorded from CA1 pyramidal neurons decreased significantly. These results demonstrate that tonically active α7 nAChRs in the CA3 field contribute significantly to the maintenance of glutamatergic synaptic activity in CA1 pyramidal neurons.

Title: Kynurenic acid and tonically active nicotinic receptors modulate resting excitability of CA1 stratum radiatum interneurons in rat hippocampal slices

Authors: E. X. ALBUQUERQUE[1], E. F. R. PEREIRA[1], *T. D. GOULD[2], M. ALKONDON[1]
[1]Div. of Translational Toxicology, Dept Epidemiology and Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD; [2]Dept Psychiat, Univ. Maryland Sch. Med., BALTIMORE, MD

Abstract: CA1 *stratum radiatum* interneurons (SRIs) express α7 nicotinic receptors (nAChRs) and receive inputs from glutamatergic neurons/axons that express α3β4β2 nAChRs. To test the hypothesis that tonically active α7 and/or α3β4β2 nAChRs control the excitability of CA1 SRIs in rat hippocampal slices, we examined the effects of selective receptor antagonists on spontaneous fast current transients (CTs) recorded from these interneurons under cell-attached configuration or AMPA EPSCs recorded in the whole-cell patch configuration. Hippocampal slices were exposed to the test chemicals by preincubation followed by bath application during the recordings. The frequency of CTs, which represent action potentials, increased in the absence of extracellular Mg^{2+} and decreased in the presence of the α3β4β2 nAChR antagonist mecamylamine (3 μM) and in the presence of kynurenic acid (KYNA, 0.2 to 2 μM). The α7 nAChR antagonist methyllycacotine (10 nM) also reduced the frequency of CTs, but only in a subset of the SRIs. Mecamylamine and KYNA also reduced the frequency of AMPA EPSCs, particularly the large-amplitude events. Thus, α3β4β2 nAChRs present on glutamatergic axons/neurons synapsing onto SRIs are activated by basal levels of acetylcholine and the tonic activity of these receptors contributes to the maintenance of the excitability of the SRIs. The suppression of action potential frequency in SRIs by submicromolar concentrations of KYNA suggests the presence of high-affinity sites for KYNA in hippocampal slices.

Title: : Long-lasting histone modifications are detected in the brains of young adult guinea pigs exposed *in utero* to the organophosphorus pesticide chlorpyrifos.

Authors: *W. R. RANDALL[1,2], R. XU[1], E. F. R. PEREIRA[2,1], E. X. ALBUQUERQUE[2,1]
[1]Pharmacol., [2]Epidemiology and Publ Hlth., Univ. Maryland Sch. Med., Baltimore, MD

Abstract: Organophosphorus (OP) pesticides such as chlorpyrifos (CPF) and malathion are among the most heavily used pest control agents worldwide. Epidemiological data indicate that OP pesticides are toxic to the developing human brain. *In-utero* exposure to OP pesticides has been linked to increased incidence of abnormal reflexes in the neonate as well as delayed mental development in young children. While the acute toxicity of OP pesticides results primarily from the rapid inhibition of acetylcholinesterase, the delayed toxicity is more likely related to long-term changes in gene expression. Our hypothesis is that *in utero* exposure to CPF alters epigenetic mechanisms, particularly histone modifications, that induce changes in the expression of genes known to control higher brain functions. To test this hypothesis, we used guinea pigs, a precocious rodent species that is considered the best non-primate model of human OP intoxication. Pregnant guinea pigs were injected subcutaneously once daily with 25 mg/kg CPF or with peanut oil (the CPF vehicle) for 10 days starting on gestation day 50-53. Guinea pigs generally delivered their pups at GD65-67. On post-natal day 60, animals were euthanized and their brains were removed. Nuclear and cytosolic fractions of brains of the animals were processed and examined by western blotting for histone modifications and intracellular proteins involved in activating histone acetyltransferases and kinases. Levels of acetyl- and phopho-histone 3 as well as levels of acetyl- and phospho-histone 2a and 2b were found to be higher in the brains of animals developmentally exposed to CPF *in utero* than in the brains of the control whose mothers were given peanut oil diluent. In addition, we observed a significant (2-fold) increase in tri-methylated histone 3 in CPF-exposed animals. The expression of p38 kinase was significantly higher in the brains of animals developmentally exposed to CPF than in the brains of control animals. This is noteworthy because p38 is one of the kinases that activates mitogen- and stress-activated kinases 1 and 2 (MSK1/2), which have been identified as the principal histone H3 kinases. Together these results suggest that exposure to CPF during early development produces epigenetic modifications in the acetylation, phosphorylation and methylation of histones 2a, 2b and 3 that could lead to long-term changes in gene expression accompanying the neuronal abnormalities observed in the deficits in cognition.

Title: An acute exposure to the organophosphorus poison VX shortens sleep episodes in guinea pigs: An electroencephalographic (EEG) analysis.

Authors: J. R. HUNT, E. ALEXANDROVA, Y. ARACAVA, E. F. R. PEREIRA, *E. X. ALBUQUERQUE
Div. of Translational Toxicology, Dept Epidemiology and Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD

Abstract: The acute toxicity of lethal doses of the organophosphorus (OP) nerve agents soman, sarin, and VX is well characterized by a cholinergic crisis that culminates on recurrent seizures. More subtle, long-lasting EEG alterations have been seen in rats intoxicated with 1xLD50 soman and in mice injected multiple times with sub-lethal doses of soman (Pharmacol Biochem Behav 42:711, 1992; Toxicology 199:59, 2004). Here, we analyzed cortical EEG recordings from guinea pigs exposed to a sub-lethal dose of VX, and/or treated with galantamine, a drug that has recently emerged as an effective therapeutic countermeasure against OP toxicity (PNAS 103: 13220, 2006). Adult male guinea pigs were implanted with a radio-telemetric electrode system (Data Sciences Intl, DSI) and maintained under light-dark 12:12 h cycle until full recovery from the surgery (10 days). On the 11th day, recordings of cortical EEG and temperature were obtained telemetrically for at least 2 h before and 6 h after with the subcutaneous injection of $0.6xLD_{50}$ VX (3.81 µg/kg) or saline (0.5 ml/kg). On the next day, recordings were continued for 2 h before treatment of the guinea pigs with galantamine (4 mg/kg, im) or saline (0.5 ml/kg, im) and for 6 h thereafter. Recordings were also obtained up to 7 days after treatments. No seizure activity was detected in EEG recordings from VX-injected guinea pigs before or after their post-treatment with saline or galantamine. Prior to the injection of VX, animals spent 36.3 ± 2.7% of the time sleeping. During the first 6 h after the VX challenge, animals spent only 14.8 ± 2.1% of the time sleeping. The VX challenge also decreased the ratio of the spectral density of the delta frequency to the total EEG power density. Twenty four hours after the VX challenge, although the total time the animals spent sleeping was comparable to control, the longest awake time of the VX-challenged guinea pigs was still significantly longer than that of control animals. By 48 h after the challenge, the sleep-wakefulness patterns and the EEG spectrum were similar to control. When animals that had been with injected with saline or VX were treated with galantamine, there was a transient reduction of the sleeping time; the effect of galantamine subsided within 1 h after the treatment. No changes were observed after injections guinea pigs with saline only. These results demonstrate that a single exposure of guinea pigs to a sub-lethal dose of VX significantly shortens sleeping time and this effect is accompanied by reduction of the delta activity. We suggest that EEG sleep-wakefulness pattern changes may be used clinically for evaluation of the effectiveness of therapeutic interventions to treat low level OP exposure.

Title: Acetylcholinesterase inhibition increases the activity of both α7 and non-α7 nAChRs in hippocampal slices

Authors: *C. R. SOURS[1], M. ALKONDON[2], E. F. R. PEREIRA[2], Y. ARACAVA[2], E. X. ALBUQUERQUE[2]
[1]Dept. of Diagnos. Radiology, Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Div. of Translational Toxicology, Dept Epidemiology Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD

Abstract: It is well known that inhibition of acetylcholinesterase (AChE), the enzyme that breaks down the neurotransmitter acetylcholine (ACh), leads to overactivation of most nicotinic receptors (nAChRs). However, there have been reports that the activity of synaptically located α7 nAChRs is not increased upon AChE inhibition (Neuron 17:1231, 1996). Studies from our laboratory have demonstrated that the excitability of CA1 stratum radiatum interneurons (SRIs) is regulated by α7 and non-α nAChRs (J Neurophysiol 86:3043, 2001). Thus, the present study was designed to determinehow the activity of hippocampal α7 and non-α7 nAChRs changes in response to AChE inhibition *in vivo* and *in vitro*. To this end, spontaneous glutamatergic excitatory postsynaptic currents (EPSCs) were recorded from CA1 SRIs in hippocampal slices obtained from 12-19-day old male guinea pigs after their subcutaneous injection with the irreversible AChE inhibitor soman (28 µg/kg). EPScs were also recorded from CA1 SRIs in rat hippocampal slices superfused *in vitro* with artificial cerebrospinal fluid containing the reversible AChE inhibitor donepezil. All recordings were obtained in the presence of the muscarinic receptor antagonist atropine (0.5 µM). In hippocampal slices obtained from guinea pigs 24 h after the injection of soman (28 µg/kg, sc) the frequency of EPSCs recorded from the SRIs was higher than that recorded from neurons in slices of control animals. *In vitro* exposure of rat hippocampal slices to donepezil (100 nM) caused a significant and sustained increase in the

frequency of EPSCs. Bath application of donepezil also increased the proportion of short (20-100 ms) inter-event intervals, indicating the presence of burst-like EPSCs. The effects of donepezil were significantly reduced by mecamylamine (10 μM) in all slices tested (n = 11). On the other hand, the α7 nAChR antagonist methyllycaconitine (10 nM) decreased the effects of donepezil in only half of the slices tested. These results suggest that enhanced levels of ACh resulting from AChE inhibition are sufficient to activate both mecamylamine-sensitive (α3β4β2) and MLA-sensitive (α7) nAChRs on glutamate neurons/axons, and thereby increase glutamate drive to the interneurons.

Title: Post-treatment with galantamine effectively counters cognitive impairment induced by exposure of adult male guinea pigs to high levels of the organophosphorus poisons soman or sarin

Authors: J. MAMCZARZ[1], J. D. PESCRILLE[1], L. GAVRUSHENKO[1], Y. ARACAVA[1], *E. J. BEECHAM[2], E. F. R. PEREIRA[1], E. X. ALBUQUERQUE[1]

Abstract: It is well known that, in the absence of any pre-treatment, an aggressive treatment with the muscarinic receptor antagonist atropine and an anticonvulsant such as diazepam or midazolam is necessary to curtail the acute toxicity of high doses of the organophosphorus (OP) poison soman and sarin. Here, we addressed the question as to whether cognitive impairment becomes evident in guinea pigs that are exposed to 1.2xLD50 soman or 2.0xLD50 sarin and post-treated with atropine, midazolam, and 2-PAM, and, if so, whether this impairment can be counteracted by inclusion of galantamine, a drug that recently emerged as an effective antidote against the acute toxicity of OP compounds (PNAS103:13220, 2006), in the post-treatment regimen. Adult (3-month-old) male guinea pigs were subcutaneously injected with 1.2xLD50 soman (29.3 μg/kg) or 2.0xLD50 sarin (63.4 μg/kg). One min after the OP challenge animals

were post-treated with atropine (2mg/kg, i.m.) and pralidoxime (25 mg/kg, i.m.), and, then, 40 min later, with midazolam (1.8 mg/kg, i.m.). Twenty four h later guinea pigs were treated with galantamine (5 mg/kg, i.m.) or saline. Three to four months after the treatments, animals were trained to find a hidden platform in a constant position in the Morris water maze (MWM). Training consisted of four trials a day over five consecutive days. Memory retention was evaluated three days later in a probe test. One week after training in the MWM, animals were transferred to a new room and received five days of reference memory training consisting of 4 trials/day in a radial 8-arm water maze (RWM). After a 2-day break, the reference memory training was continued in a one-trial-a-day paradigm for two more days. On the 8th day of RWM training, the platform was moved to the opposite arm and training continued in the one-trial-a-day paradigm. When compared to control (animals injected with saline only), guinea pigs that had been challenged with soman or sarin and post-treated with atropine, midazolam, and 2-PAM showed learning impairment in the MWM. These animals also presented with deficits in the formation of new memories in the RWM. Inclusion of galantamine in the post-treatment regimen completely abolished the adverse effect of soman on cognition. These results demonstrate that cognitive impairments do become evident long after an exposure of guinea pigs to high doses of soman or sarin, despite the post-treatment with atropine, midazolam, and 2-PAM, and are effectively countered by inclusion of galantamine in the post-treatment regimen.

Title: Butyrylcholinesterase and cholinergic neural elements in the mouse brain

Authors: *S. DARVESH[1,2], G. A. REID[2], N. CHILUKURI[3]
[1]Dept Med. Anat & Neurobiol, Dalhousie Univ. QEII Hlth. Sci. Ctr., Halifax, NS, Canada; [2]Anat. & Neurobio., Dalhousie Univ., Halifax, NS, Canada; [3]Physiol. & Immunol. Br., US Army Med. Res. Inst. of Chem. Def., Aberdeen, MD

Abstract: Introduction: The cholinergic neurotransmitter acetylcholine is synthesized by choline acetyltransferase (ChAT) and its action terminated by the enzymes acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE). While the role of AChE in cholinergic regulation has been studied extensively, that of BuChE remains to be explored. The present work was therefore undertaken to map the distribution of BuChE and examine its colocalization with cholinergic neural elements.
Methods: 129S1/SvImJ mice were used to map the distribution of BuChE and determine its relationship to the cholinergic neurotransmitter system. Brain tissue was stained for BuChE activity, using a modified Karnovsky-Roots histochemical method, and ChAT, using immunohistochemistry. Immunofluorescent double labeling was used to demonstrate colocalization of BuChE and ChAT.
Results: In the mouse, BuChE staining labeled neurons, neuropil, white matter and glial cells, while ChAT labeled neurons and neuropil. Areas with BuChE-positive neurons included the anterior and lateral thalamic groups, medial amygdala, lateral hypothalamus and several cranial nerve nuclei. BuChE and ChAT neuronal colocalization was largely confined to the brainstem, with the dorsal motor nucleus of the vagus nerve, hypoglossal nucleus, facial nucleus, inferior salivatory, and the noradrenaline cell group A5 all having numerous neurons with both markers. A close relationship was also observed between BuChE positive neuropil and ChAT positive perikarya in the tegmentum. ChAT positive neuropil was also found in areas with BuChE positive neurons such as the medial entorhinal cortex.
Discussion & Conclusions: BuChE staining of neural elements was found in a number of regions of the mouse brain. There was a close relationship between the distribution of BuChE and ChAT in certain areas of the neuraxis. The staining patterns between these two enzymes included neuronal colocalization, BuChE neuropil enveloping cholinergic neurons, and BuChE neurons found in areas with ChAT neuropil. This close relationship between BuChE and cholinergic neural elements implies that BuChE is involved in cholinergic neurotransmission.

Title: An *in vitro* neuronal model to study organophosphorus (OP) nerve agent mechanisms of action and countermeasures

Authors: B. KEYSER, B. KANJILAL, D. ANDRES, E. NEALLEY, B. BENTON, A. APPELL, A. GRIGOROVITCH, *R. RAY
USA Med. Res. Inst. Chem Def., Aberdeen Prv Gr, MD

Abstract: The OP nerve agents (NA) soman, sarin, tabun and VX act principally as potent cholinesterase inhibitors; this inhibition causes a cholinergic crisis due to a buildup of excess acetylcholine (ACh) at both peripheral and central nervous system (CNS) synapses. In the CNS, this cholinergic abnormality is believed to trigger a glumatergic response, which contributes to convulsions and subsequent damage to postsynaptic neurons. The limitations of the current therapeutic regimen, i.e., atropine, 2-PAM (2-pyridine aldoxime methyl chloride) and an anticonvulsant compound (diazepam) are that (a) these compounds do not offer an adequate protection against both central and peripheral effects and (b) there is no neuroprotection to prevent the subsequent neuronal damage. However, the progress in developing an ideal therapeutic approach has been hindered by the lack of an appropriate in vitro model that can be used to investigate the possible mechanisms of toxicity and the prospective therapeutic interventions prior to their validation in a suitable animal model. Since nerve agents target neurons in both the central and the peripheral nervous systems, using a cell line that incorporates properties of both central and peripheral neurons would be advantageous. We, therefore, studied the cultured human neuroblastoma N18TG2 and motor neuron-enriched embryonic mouse spinal cord hybrid NSC-34 cell line as a potential neuronal model. NSC-34 cells possess cholinergic properties, e.g., action potential generation, expression of choline acetyltransferase, synthesis and storage of ACh, and neurotransmitter release function. Moreover, differentiating these cells by serum deprivation or altering medium composition makes these cells sensitive to glutamate stimulation. Our results show that differentiated NSC-34 cells undergo cell death due to glutamate toxicity/exposure (0.1 – 20 mM, 24 hrs) as determined by caspase-3 activation and annexin V/propidium iodide flow cytometric analyses. We have also studied the effects of the nerve agent VX on these cells. Results show that NSC-34 cells exposed to VX (10 – 100 nM, 18-24 hrs) exhibit a significant ($p<0.05$) increase in caspase-3 activation, a key enzyme in apoptotic cell death. In addition, VX-treated cells exhibit some morphological changes such as enhanced levels of vacuole formation, which is indicative of cell death. Taken together, these results demonstrate that NSC-34 cells are sensitive to both VX and glutamate; however, whether glutamate is directly involved in the VX effect needs to be established.

Title: Distinguishing the distinct contributions of the Group II metabotropic glutamate receptor subtypes (mGlu2 & mGlu3) in modulating somatosensory transmission *in vivo*

Authors: *T. E. SALT, S. A. NEALE, C. S. COPELAND
UCL Inst. Ophthalmology, London, United Kingdom

Abstract: Group II metabotropic glutamate (mGlu) receptor (mGlu2/3) modulation of somatosensory transmission in the rat ventrobasal thalamus (VB) [1] was recently identified by ourselves to have an mGlu2 component to the overall Group II effect on sensory inhibition [2]. However, due to a paucity in mGlu3 selective pharmacological tools, it has not been possible to draw a concurrent conclusion regarding the role of mGlu3 subtype in modulating this sensory inhibition, until now. Extracellular single-neurone recordings were made in vivo with multi-barrel iontophoretic electrodes in the VB of urethane-anaesthetized male Wistar rats (365-420g). Procedures were Home Office (UK) approved and accorded with the Animals (Scientific Procedures) Act 1986. Single vibrissae were stimulated and mGlu agents were applied while stimulating principal and secondary vibrissae and recording from corresponding single VB neurones.
By using the dual mGlu2 agonist/mGlu3 antagonist LY395756 (5mM, pH 8, 75mM saline) we can hypothesize that the Group II effect on sensory inhibition is largely mediated through activation of mGlu3: when applied alone, the predominant of effect of LY395756 was that of antagonism as responses to short-duration stimulation (10-30ms) of the principal vibrissa were reduced (59% ±8% of control) along with a concurrent increase in sensory inhibition evoked by stimulation of a secondary vibrissa (12% ±2% increase in sensory inhibition) - an effect similar to the Group II antagonist LY341495 under the same conditions [2]. This also intimates that mGlu3 is activated by ‘glutamate spillover’ upon physiological sensory stimulation. In addition, we have provided further evidence that there is indeed an mGlu2 component to the Group II effect on sensory inhibition as, when co-applied with the mGlu2 selective positive allosteric modulator (PAM) LY487379 (1mM, pH 6, 1% DMSO, 75mM saline), there was an apparent

reversal in the action of LY395756 as an increase in responses to short-duration stimulation (117% ±2% of control) was observed, along with a concurrent decrease in sensory inhibition (21% ±2% decrease in sensory inhibition). This is an effect similar to the Group II agonist LY354740 under the same conditions [2] and can be attributed to the PAM revealing the underlying mGlu2 agonism component of LY395756.
Thus we suggest Group II receptor modulation of somatosensory transmission in VB is largely mediated by mGlu3, with only a small mGlu2 component, and that selective mGlu3 compounds might modify function of sensory, attentional and cognitive processes.

Title: Effects of xanthurenic acid on synaptic transmission in the mouse hippocampus

Authors: *S. A. NEALE[1], C. S. COPELAND[2], T. E. SALT[2]
[1]Neurexpert, Kent, United Kingdom; [2]Visual Neurosci., UCL Inst. of Ophthalmology, London, United Kingdom

Abstract: Xanthurenic acid (XA), a molecule arising from tryptophan metabolism, has been proposed to act as a signalling molecule in the CNS, perhaps via modulation of Group II metabotropic glutamate (mGlu) receptors[1,2]. It has previously been demonstrated that mGlu receptors modulate synaptic transmission in many brain regions, including the hippocampus. We have, therefore, investigated the effects of XA on synaptic transmission in the *in vitro* hippocampal slice preparation of adult C57BL/6 mice with extracellular field recording. In the dentate gyrus, stimulation of the perforant path resulted in excitatory post-synaptic potentials (EPSPs) which were depressed in amplitude upon application of the Group II mGlu receptor agonist LY354740 (10 nM-1 μM; with 1 uM reducing EPSP amplitude to 24 ± 2% of control levels) and this depression was associated with a clear change in the EPSP2:1 paired-pulse ratio from 93 ± 2% to 126 ± 5%. Application of XA (0.1-3 mM) resulted in a concentration-dependent depression of EPSP amplitude (3 mM; 75 ± 2% of control amplitude) which reversed on washout. This depression persisted in the presence of GABA receptor antagonists and was

associated with a small, albeit statistically significant change in the paired-pulse ratio (91 ± 3% to 95 ± 3%; n = 6; P = 0.001), suggesting a presynaptic effect on glutamate release. The effects of XA were modest in comparison to LY354740 and, in contrast to LY354740, were not reversed in the presence of the Group II antagonist LY341495 (300 nM). Furthermore, co-application of XA (0.1-0.3 mM) with LY354740 (10-30 nM) showed no increase in effect compared to the EPSP depression evoked by LY354740 alone. In the CA1 region, the amplitudes of EPSPs evoked by stimulation of the Schaffer collateral/commissural pathway were unaffected by LY354740 (1 μM; 101 ± 2% of control amplitude), whereas XA produced a depression (3 mM; 80 ± 6% of control amplitude) which fully reversed on wash. We have previously demonstrated an effect of XA on sensory processing in the thalamus via modulation of GABA receptor-mediated neurotransmission[3]. Consistent with XA modulating GABAergic signalling, in the CA1 recordings XA (3 mM) produced changes in the EPSP waveform indicative of a reduction in inhibition. In summary, these data suggest XA may indeed be a potential neuromodulator; however, in the hippocampus this action appears to be via mechanisms independent of Group II mGlu receptor activation.

Abstract: The mediodorsal thalamic nucleus (MD), which relays information from the amygdala to the prefrontal cortex (PFC) and limbic system, has been heavily implicated in the

pathophysiology of schizophrenia, as has gating within the thalamic reticular nucleus (TRN), a GABAergic nucleus located between the thalamus and cortex, with which the MD makes reciprocal connections. Group II metabotropic glutamate (mGlu) receptor agonists and positive allosteric modulators have proved efficacious in a number of animal models of schizophrenia and a phase II clinical trial, and have been shown to modulate somatosensory transmission within the rat ventrobasal thalamus (VB) by reducing inhibition originating from the TRN [1,2]. We have therefore examined whether Group II mGlu receptor activation can modulate neurotransmission in the MD upon stimulation of the PFC and amygdala. Extracellular single-neurone recordings were made in vivo with multi-barrel iontophoretic electrodes in the MD of urethane-anaesthetized male Wistar rats (320-420g). Procedures were Home Office (UK) approved and accorded with the Animals (Scientific Procedures) Act 1986. The PFC and amygdala were electrically stimulated using concentric bipolar electrodes, and mGlu agents were iontophoretically applied whilst recording from single MD neurones.
Inhibition evoked in the MD upon stimulation of the amygdala was reduced upon iontophoretic application of the Group II mGlu receptor agonist LY356740 (5mM, pH 8, 75mM saline) (27%±16% reduction in inhibition), and was increased upon application of the Group II mGlu receptor antagonist LY341495 (5mM, pH 8, 75mM saline) (77% increase in inhibition). This action of Group II mGlu receptor modulation of thalamic inhibition is similar to that observed in the VB upon principal vibrissa stimulation (1,2). In addition, the duration of long-latency inhibition evoked upon stimulation of the PFC was reduced upon application of LY354740 (80ms ±20ms reduction in long-latency inhibition duration).
Group II mGlu receptor modulation of inhibition evoked in thalamic relay nuclei may therefore represent an over-arching principle for all thalamic nuclei. In addition, Group II mGlu receptor modulation of neurotransmission within the MD may prove to be important in selective attention and cognitive processing.

Abstract: Metabotropic glutamate (mGlu) receptors regulate the activity of the thalamic-cortical-thalamic network that is involved in the generation of absence seizures. We have shown that allosteric potentiation of mGlu1 receptors reduces spike and wave discharges (SWDs) in the WAG/Rij rat model of absence epilepsy, whereas activation of mGlu2/3 and mGlu4 receptors enhances SWD frequency. Here, we extended the study to mGlu5 receptors using the novel mGlu5 receptor enhancer, VU0360172.6. WAG/Rij rats showed a reduction in the mGlu5 receptor protein levels and in the mGlu5 receptor signalling in the ventrobasal thalamus, and an increased expression of mGlu5 receptors in the somatosensory cortex, as compared with non-epileptic control rats. At least some of these changes were already present in young WAG/Rij rats, at an age that preceded the onset of absence seizures. Pharmacological blockade of mGlu5 receptors with MTEP (10 or 30 mg/kg, i.p.) did not affect SWDs in WAG/Rij rats. In contrast, treatment with the mGlu5 receptor enhancer, VU0360172-6 (3 or 10 mg/kg, s.c.), significantly reduced absence seizures without affecting motor behaviour. The action of VU0360172-6 was antagonized by MTEP. These findings suggest that changes in mGlu5 receptors contributes to the pathophysiology of absence seizures in WAG/Rij rats, and that drugs that potentiate the activity of mGlu5 receptors are potential candidates to the treatment of absence epilepsy.

Title: Role of the metabotropic glutamate receptor mGluR7 at a thalamic reticular synapse

Authors: *F. BERTASO, V. TASSIN, L. FAGNI
Inst. Functional Genomics, Montpellier, France

Abstract: The metabotropic glutamate receptor, mGluR7, is a presynaptic receptor that inhibits neurotransmitter release upon elevated synaptic activity. We have shown that inactivation of this receptor causes absence-like epileptic seizures in rodents, which result from thalamo-cortical loop dysfunction. The present study aimed at understanding the specific function of the receptor in synaptic transmission. To this end we used in vitro mouse thalamo-cortical slices and patch-clamp recording in wild-type and transgenic knock-in mice bearing a non functional mGluR7 receptor (mGluR7AAA). We found that the mGluR7/4/8 agonist D,L-AP4 (1.2 mM) inhibited excitatory post-synaptic currents (EPSCs) between thalamic relay cells and thalamic reticular neurons in wild type, but not in mGluR7AAA neurons. This result suggests that mGluR7 is functionally expressed in this synapse. The majority of thalamic inputs on wild-type reticular neurons displayed paired-pulse depression of EPSCs, behaving as classical "drivers" of the reticular neurons. Conversely, paired-pulse facilitation of synaptic transmission was recorded in the majority of mGluR7AAA knock-in reticular neurons. These data suggest that reticular activity can be amplified in the absence of a functional mGluR7, thus inducing a hyper-inhibition of thalamic relay neurons, which in turn may trigger thalamo-cortical loop oscillation. Induction of absence epilepsy by mGluR7 inactivation may therefore results from defects of this pathway.

Title: mGluR5 signaling in cortical glutamatergic neurons - Regulate cortical excitability

Authors: *H. SUN, C. J. BALLESTER ROSADO, C.-S. WU, C. P. JEW, D.-H. YU, H.-C. LU
Dept. of Pediatrics and Neurol., Baylor Col. of Med., Houston, TX

Abstract: Signaling by the group I metabotropic glutamate receptor 5 (mGluR5) in cortical glutamatergic neurons is required for the development of whisker-related patterns in the primary somatosensory cortex (REF: Carlos's paper in JN). Proper excitation/inhibition balance is crucial for sensory perception. Deleting mGluR5 in glutamatergic neurons affects the functional development of GABAergic circuits projected onto glutamatergic neurons. We hypothesis that mGluR5 signaling in cortical glutamatergic neurons is required to regulate cortical excitability. We explored this hypothesis using a mouse genetic approach with electrophysiological experiments in acute brain slices and intact mice as well as a range of behavioral paradigms. At the cellular level, we found an increase in the frequency in spontaneous events in cortical layer IV glutamatergic neurons with cortex-glutamatergic mGluR5 conditional knock-out (Cx-Glu-cKO) and their littermate control mice. Consistent with the increased excitability at the neuronal level, the threshold to induce status epilepticus by kainic acid was reduced in Cx-Glu-cKO mice. At the behavioral level, Cx-Glu-cKO mice exhibit enhanced novelty-induced locomotion, with no obvious deficits in either contextual or auditory-cue conditioned fear. mGluR5 deletion has been found in a subset of patients with Attention Deficit Hyperactivity Disorder (ADHD) (REF: Nat. Genetics paper by Hankonarson). Our finding suggests that the genetic disabling of mGluR5 in glutamatergic neurons leads to an overall increase in cortical excitability, which may contribute to ADHD behaviors.

Title: Snare proteins are essential in the potentiation of NMDA receptors by group II metabotropic glutamate receptors

Authors: *J. CHENG, W. LIU, Z. YAN
Physiol. and Biophysics, State Univ. of New York At Buffalo, Buffalo, NY

Abstract: The group II metabotropic glutamate receptor (mGluRII) has emerged as a new drug target for schizophrenia treatment. To understand the potential molecular mechanisms underlying the antipsychotic effects of mGluRII, we examined its impact on NMDA receptors, since NMDAR hypofunction has been implicated in schizophrenia. We previously found that application of APDC, a highly selective mGluRII agonist, caused a potent enhancement of NMDAR-mediated currents in cortical pyramidal neurons. Here we examined whether this effect of mGluRII involves the exocytosis of NMDA receptors mediated by SNARE proteins, such as SNAP-25 (synaptosomal-associated protein of 25 kDa) and Syntaxin 4. We found that the enhancing effect of APDC on NMDAR currents was abolished when SNARE complex was disrupted by delivering Botulinum toxin or SNAP-25 C-terminal blocking peptide into the neurons. Moreover, knockdown of Syntaxin 4 blocked mGluRII potentiation of NMDAR currents. Syntaxin 4 is a postsynaptic component interacting with Rab4, a small Rab GTPase mediating fast recycling from early endosome to the plasma membrane. The effect of APDC on NMDAR currents was abolished by dominant negative Rab4, and occluded by constitutively active Rab4, suggesting the involvement of Rab4-mediated NMDAR exocytosis to the cell membrane. Taken together, these results have revealed the key molecules involved in mGluRII enhancement of NMDA receptor trafficking and function.

Title: WIN55, 212 attenuates NMDA- but not kainate-induced hippocampal seizures via mGluR1α and CB1 receptors during a critical period

Authors: *L. K. FRIEDMAN, V. RUDENKO
NYCOM/NYIT, Old Westbury, NY

Abstract: In adult rats, the synthetic cannabinoid agonist, WIN55212, suppresses spontaneous seizure activity and IPSCs of DHPG-sensitive hippocampal neurons. Anticonvulsant effects were attributed to reducing pre-synaptic release of glutamate via G-protein coupled CB1 receptors. In postnatal (P) day 20 rats, we found that kainate (KA)-induced epileptic activity is inversely related to WIN55212 dosage after peripheral injection. Higher doses were proconvulsant and injurious whereas lower doses were anticonvulsant and neuroprotective. To determine whether

this inverse relationship on the seizure threshold occurs in the P20 hippocampus, stereotaxic microinfusions of WIN55212 (0.5 µg) were delivered to the CA1 followed by NMDA (0.1 µg) or KA (0.3 µg) in the presence and absence of LY367385, MPEP or AM251. Electroencephalography (EEG) recordings were simultaneously determined with a bipolar/cannula assembly. CB1 and NMDA receptor proteins were examined. Unilateral intrahippocampal WIN 55,212 alone caused rapid sedation and low amplitude synchronous oscillations in the EEG. In the presence of WIN55212, NMDA-induced epileptic currents were delayed and attenuated. Blockade of mGluR1α receptors with LY367385 or CB1 receptors with AM251 (but not MPEP) prevented the attenuation. In contrast, microinfusion of a saturating concentration of KA after WIN55212, led to increased periodic oscillations containing high frequency spikes. Immunohistochemistry revealed a dose-dependent reduction in CB1 receptor expression with increasing concentrations of WIN55212 in presence or absence of KA seizures. There were steady or increased levels of mGluR1α subunits within interneurons and variable distribution of NR1 and NMDA C2 terminal splice variant expression within pyramidal cells. Differential responses of NMDA and KA on seizure threshold subsequent to WIN55212 application suggests selective cooperation whereby NMDA is expected to co-activate postsynaptic mGluR group I receptors to synergistically activate release of endocannabinoids to further attenuate EEG spiking. Consistent with studies showing LY367385 increases short-term facilitation, particularly in young, we illustrate that mGluR1α subunits and CB1 receptors appear required for the efficacious inhibitory actions of WIN5521 on NMDA currents and that KA receptor activation is not coupled to the cannabinoid/mGluR pathway. CB1 receptor spatiotemporal re-distributions caused by seizures as a function of age may also impart different action on regulatory mechanisms of transmitter release to control the seizure threshold and associated brain injury.

Title: Astroglial metabotropic glutamate receptor 3 promotes the non-amyloidogenic pathway by modulating alpha and beta secretase expression

Authors: D. DURAND[1], L. CARNIGLIA[1], C. CARUSO[1], *M. I. LASAGA[2]
[1]INBIOMED, [2]Res. Ctr. in Rerpoduction, Sch. of Med. Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: Alzheimer's disease is characterized by the presence of amyloid β (Aβ) plaques in the brain. Aβ derives from proteolytic cleavage of amyloid precursor protein (APP) by β- (BACE) and γ-secretases. On the other hand, α-secretase cleaves APP within the Aβ domain generating a soluble fragment (sAPPα) which shows neuroprotective effects and improves memory. ADAM-10 and ADAM-17 metalloproteases have been identified as the main α-secretases expressed in the brain. Group II metabotropic glutamate receptors (mGluR) include mGlu3R and mGlu2R, being mGlu3R expressed in astrocytes. Astroglial mGlu3R activation reduces neuronal degeneration induced by Aβ in vitro. Although it has been shown that a non-selective agonist of mGluR promotes the non-amyloidogenic pathway in astrocytes, most likely by activating group II mGluR, this issue has not been further explored. Therefore, we studied the involvement of mGlu3R in the non-amyloidogenic shedding of APP in primary cultured rat astrocytes.
The mGlu3R-selective agonist LY379268 increased sAPPα release from astrocytes in a dose-dependent manner (LY0.01 μM $p<0.05$; LY0.1 μM and LY10 μM $p<0.01$ versus control). In congruence with these results, ADAM-10 and ADAM-17 gene and protein expression was induced by LY379268 (0.1-10 μM), as assassed by qRT-PCR and western-blot (ADAM-17: LY 0.1 and 1 μM $p<0.01$; LY 10 μM $p<0.05$; ADAM-10: LY 0.1 and 10 μM $p<0.05$; LY 1 μM $p<0.001$ versus control). Conversely, BACE1 protein levels were significantly reduced after LY379268 treatment (LY 0.1 and 10 μM $p<0.001$; LY 1 μM $p<0.05$ versus control). The effect of LY379268 on sAPPα production was not observed in the presence of an antagonist of the peroxisome proliferator activated receptor (PPAR)-γ (GW9662 2 μM). Surprisingly, LY379268 reduced PPAR-γ protein expression (LY 0.1 μM $p<0.05$; LY1 and 10 μM $p<0.001$), thus further study is needed to clarify the involvement of this nuclear receptor in the non-amyloidogenic shedding of astroglial APP.
Our data indicate that mGlu3R activation promotes the non-amyloidogenic pathway, shifting APP proteolysis towards sAPPα production in astrocytes, through ADAM-10 and ADAM-17 up-regulation and BACE1 down-regulation. This study provides evidence for a new molecular mechanism accounting for the neuroprotective effects of astrocytic mGlu3R on Aβ neurotoxicity.

Title: Functional expression of metabotropic glutamate receptors in mouse optic nerve astrocyte

Authors: *I. VANZULLI, A. M. BUTT
Inst. of Biomed. and Biomolecular Sci., Univ. of Portsmouth, Portsmouth, United Kingdom

Abstract: Metabotropic glutamate receptors (mGluRs) are seven transmembrane domain G-protein-coupled receptors for L-glutamate, the main excitatory neurotransmitter in the mammalian brain. Here, we analyzed the functional expression of mGluRs in astrocytes of the mouse optic nerve, a white matter tract of the central nervous system that contains neither neuronal cell bodies nor synapses. Calcium imaging experiments were performed in optic nerves from P9-13 wild-type CFLP mice; all procedures were in accordance with the Animal Scientific Procedures Act (1986). Optic nerves were isolated intact and loaded with fluo-4 AM. Nerves were visualized using a Zeiss LSM 5 Pascal Axioskop 2 confocal microscope; images were collected in optical z-sections and changes in fluorescence intensity were measured. The application of mGluR agonists ACPD and DHPG showed that group I mGluRs, which are coupled to the $G_{q/11}$ protein, mediate a rise in glial $[Ca^{2+}]_i$. The action of the group I mGluR antagonist AIDA versus ACPD indicated that the rise in $[Ca^{2+}]_i$ also involves group II and group III receptors, which are negatively coupled to adenylate cyclase through the G_i family of G-proteins. Immunohistochemistry showed that group I subunit mGluR5 and group II subunits mGluR2 and mGluR3 colocalize to both astrocytes and pericytes at the gliovascular interface. The results demonstrate functional mGluRs in optic nerve astrocytes and support a role in neurovascular coupling. Further experiments are required to determine the role of these receptors in driving glial cell coupling of blood flow to axonal activity in the optic nerve white matter.

Title: Impaired activity-dependent fmrp translation in fragile x premutation mice

Authors: A. J. RENOUX[1], A. J. ILIFF[2], A. KRANS[3], K. USDIN[5], P. K. TODD[3], *M. A. SUTTON[4]
[1]Physiol., [2]MBNI/Neuroscience, [3]Neurol., [4]MBNI/Physiology, Univ. Michigan, Ann Arbor, MI; [5]Natl. Inst. of Diabetes, Digestive, and Kidney Dis., NIH, Bethesda, MD

Abstract: Neuronal function and cognition are dependent on normal synaptic responses to activity and impairments in synaptic plasticity are thought to underlie disorders such as Fragile X Syndrome (FXS) and autism. One protein important for the regulation of synaptic plasticity is the RNA-binding fragile X mental retardation protein (FMRP), which acts to inhibit translation the synapse. Activation of metabotropic glutamate receptors (mGluRs) triggers FMRP degradation, resulting in rapid synthesis of several proteins, including FMRP itself. Ultimately, mGluR activation produces a temporally constrained window of local protein synthesis. FMRP is known to play an important role in mGluR-dependent plasticity, but the specific role of activity-dependent translation of FMRP in synaptic plasticity is unknown. To approach this question, we utilized a CGG knock-in mouse model of the Fragile X premutation. This model has 120 CGG repeats in the mouse FMR1 5'UTR resulting in increased Fmr1 mRNA production but impaired FMRP translational efficiency, resulting in lower basal expression of FMRP. Cultured hippocampal neurons and cortical synaptoneurosomes derived from CGG KI mice demonstrate impaired FMRP translation in response to the group I mGluR agonist DHPG. The consequences of this impaired FMRP translation are currently under investigation. Together, these studies support a role for activity-dependent synthesis of FMRP in synaptic function and Fragile X premutation associated disorders.

Title: Reduction of prodynorphin gene expression prevents memory impairment related to aging via group 1 metabotropic glutamate receptor function

Authors: *C. MENARD[1], Y. C. TSE[1], J.-G. CHABOT[1], H. HERZOG[2], C. SCHWARZER[3], T. P. WONG[1], R. QUIRION[1]
[1]Neurosci., DMHUI, McGill Univ., Montreal, QC, Canada; [2]Garvan Inst. of Med. Research, Univ. of New South Wales, Sydney, Australia; [3]Dept. of Pharmacology, Innsbruck Med. Inst., Innsbruck, Austria

Abstract: Expression of dynorphin, an endogenous opioid peptide, increased with age in the hippocampus of rodents. This up-regulation has been associated with memory impairment. In human, elevated dynorphin expression has been reported in Alzheimer's disease. Moreover, prodynorphin (Pdyn) gene polymorphisms have been linked to cognitive function in the elderly. Using Pdyn knockout (KO) mice, we investigated the impact of dynorphin expression on memory during aging. Group 1 metabotropic glutamate receptor (mGluR) function is essential for successful cognitive aging. We compared mGluR1α and mGluR5 levels in Pdyn KO and wild-type (WT) mice hippocampal formation. While protein levels are similar in young animals (5-7 months), mGluR1α and mGluR5 were increased by 63% and 110% in old Pdyn KO mice (18-25 months) with no changes for WT. Synaptic plasticity is crucial to maintain cognitive abilities and long-term depression (LTD) induced by group 1 mGluR activation has been linked to memory in the aging brain. Dihydroxyphenylglycine, a selective mGluR1α/mGluR5 agonist, was applied to hippocampal slices from old Pdyn and WT mice. mGluR-LTD was significantly enhanced in Pdyn KO mice CA1 region (30% vs 4% for WT). mGluR-mediated plasticity has been highly implicated for hippocampal memory formation, suggesting Pdyn KO should display better cognitive function. In young mice, no differences were observed in the Morris Water Maze (WM) task. However while old WT mice developed memory deficits, aged Pdyn KO mice performances were similar to young subjects, suggesting intact cognition. Reverse memory and inhibitory learning, processes known to be affected by aging, were also preserved in old mice lacking Pdyn gene. Immediate early gene translation is induced by mGluR-LTD and necessary to consolidate memories. Following WM training, Homer 1a and Arc expression was 1.4 fold higher in aged Pdyn KO mice compared to WT, supporting intact memory processes despite aging. In an object recognition test, old Pdyn KO animals show intact reference memory as well. Anxiety which affects cognition generally increases with age. Dynorphin peptides enhance stress responses and anxiety-related behaviors. In line with high Pdyn expression in aged WT mice, we observed an anxiolytic phenotype for Pdyn KO mice with longer distance travelled in the elevated plus maze open arms. Low anxiety level for mice lacking Pdyn gene was confirmed with the novelty-suppressed feeding test. Indeed, Pdyn KO mice took 50% less time than WT to start feeding. Our results suggest that an increase in mGluR expression in Pdyn KO mice contributes to successful aging by enhancing cognitive abilities and reducing psychiatric burdens.

Title: Differences in serotonergic and glutamatergic receptor binding between the Roman Low- (RLA-I) and High (RHA-I) avoidance rat strains

Authors: *A. B. KLEIN[1], L. ULTVED[1], M. SANTINI[1], A. TOBEÑA[2], A. FERNANDEZ-TERUEL[2], P. FLORES[3], M. MORENO[3], G. M. KNUDSEN[1], S. AZNAR[1], J. D. MIKKELSEN[1]
[1]Copenhagen Univ. Hosp., Copenhagen, Denmark; [2]Univ. Autonoma de Barcelona, Barcelona, Spain; [3]Univ. de Almería, Almería, Spain

Abstract: The Roman low- and high-avoidance rat strains (RLA-I vs RHA-I) have been bidirectionally selected and bred in accordance with their performance in the two-way active avoidance response in the shuttle-box test. Subsequently, numerous studies have reported a pronounced divergence in emotionality between the two rat strains including differences in novelty seeking, anxiety, stress coping, and susceptibility to addictive substances. However, the underlying molecular mechanisms behind these divergent phenotypes are not known. Previous reports describe lower levels of serotonin and noradrenaline in the striatum and nucleus accumbens. Here, we determined levels of 5-HT_{2A}, 5-HT_{1A} and serotonin transporter binding using highly specific radioligands (^{3}H-MDL100907, ^{3}H-WAY100635 and ^{3}H-escitalopram) and mGluR2/3 binding (^{3}H-LY341495) using receptor autoradiography in fronto-cortical sections from RLA-I (n=8) & RHA-I (n=8) male rats. In RHA-I rats, 5-HT_{2A}, 5-HT_{1A} and SERT binding in frontal cortex were significantly higher (18%, 15% and 24%, respectively) compared to RLA-I rats. In contrast, mGluR2/3 binding was decreased by 40% RHA-I rats compared to RLA-I rats in the same brain region. To differentiate between mGluR2 and mGluR3, levels of these mRNA transcripts were further studied using RT-qPCR, and showed a marked reduction (63%) in mGluR2 mRNA levels, while no differences was observed in mGluR3 mRNA levels. Collectively, these data show general differences in the serotonergic system and a pronounced

difference in mGluR2/3 binding, which presumably is due to a large decrease in mGluR2 transcription in RHA-I rats. These changes may be mediating some of the phenotypic characteristics in this strain, e.g. increase in impulsivity and susceptibility to drug addiction.

Title: Plasticity of group II metabotropic glutamate receptors in regulating hypothalamic excitability in hypertension

Authors: *Z.-Y. YE, H.-L. PAN
Dept of Anesthesiol. and Perioperative Med., The Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: Increased glutamatergic input to the paraventricular nucleus (PVN) of hypothalamus plays a critical role in the development of neurogenic hypertension. However, the contribution of metabotropic glutamate receptors (mGluRs) is not clear. Here we determined the role of inhibitory group II mGluRs in controlling excitatory and inhibitory synaptic inputs to retrogradely labeled spinally projecting PVN neurons in spontaneously hypertensive rats (SHRs). Activation of group II mGluRs with the agonist DCG-IV produced a greater dose-dependent inhibitory effect on the frequency, but not the amplitude, of spontaneous excitatory postsynaptic currents (EPSCs) in SHRs than in normotensive Wistar-Kyoto (WKY) rats. This effect was not altered by tetrodotoxin. DCG-IV also caused a greater inhibition of evoked EPSCs in SHRs than in WKY rats, and such an effect was not changed by including GDP-β-s in the pipette recording solution or by blocking the glia activity with fluoroacetate. Bath application of the group II mGluR antagonist LY341495 alone has no significant effect on the baseline EPSCs, although it abolished the inhibitory effect of DCG-IV. Lowering the blood pressure with celiac ganglionectomy in SHRs normalized the potentiated inhibition of EPSCs by DCG-IV. In addition, DCG-IV produced a similar inhibitory effect on GABAergic inhibitory postsynaptic currents of labeled PVN neurons in WKY rats and SHRs. However, DCG-IV inhibited the firing

activity of labeled PVN neurons in SHRs but not in WKY rats. Together, our findings provide new information that the activity of group II mGluRs is increased at the glutamatergic terminals in the PVN, which influences the glutamatergic input and firing activity of PVN presympathetic neurons in hypertension.

Abstract: In Parkinson's disease (PD) the progressive loss of nigro-striatal neurons leads to a decreased activity of the direct pathway and an increased activity of the indirect pathway, which lead to inhibition of thalamocortical neurons and motor dysfunction. Dopamine released from the nigro-striatal pathway stimulates the direct pathway acting at D1 receptors and inhibits the indirect pathway acting at D2 receptors. Activation of mGlu4 receptors inhibits GABA release at the synapse between stratial projection neurons and neurons of the external globus pallidus. This is the first synapse of the indirect pathway of the basal ganglia motor circuit, which is overactive in PD. Drugs that activate mGlu4 receptors cause a robust depression of inhibitory synaptic transmission in the external globus pallidus, relieve motor symptoms and induce neuroprotective effects in animal models of parkinsonism. It is generally believed that during the early "compensated" phase of PD a number of mechanisms reduce the activity of the indirect pathway. Whether mGlu4 receptors undergo plastic modification during the early "compensated" phase of PD is unknown. We examined the transcripts of mGlu4 receptors and other proteins involved in the regulation of basal ganglia motor circuit in mice challenged with the parkinsonian toxin, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and with the dopamine receptor blocker, haloperidol. We found an up-regulation of mGlu4 receptor, CB1 receptor, and preproenkephalin-A mRNA at early times following injection of MPTP (30 mg/kg, i.p.) which kills about 50% of

nigro-striatal dopaminergic, as well as following a single injection haloperidol (1 mg/kg, s.c.). No changes were found in the transcripts of mGlu5 receptors, A2A receptors and the potassium/chloride co-transporter, KCC2. The increase in the number of c-Fos-expressing neurons in the external globus pallidus seen at early times following MPTP injection was absent in mGlu4 receptor knockout mice. These data suggest that an up-regulation of mGlu4 receptors in striatal projection neurons contributes to restrain the activity of the indirect pathway in the early phases of parkinsonism.

Title: Effects of mGluR8-selective compounds in the lateral and medial perforant path inputs to the dentate gyrus

Authors: *M. MERCIER, Z. BORTOLOTTO, G. COLLINGRIDGE, D. LODGE
Physiol. & Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstract: Metabotropic glutamate receptors (mGluRs) are classified into three groups (I-III) based on sequence homology, transduction mechanisms and pharmacological profiles. Group III mGluRs (mGluR4/6/7/8) have received little attention relative to either group I (mGluR1/5) or II (mGluR2/3), despite being linked to a variety of neurological and psychiatric conditions including anxiety and epilepsy. This may in part be due to the paucity of selective pharmacological tools available for these receptors. However, important advances have recently been made in the development of group III mGluR subtype-selective compounds. Namely, the actions of an mGluR8-selective agonist, (*S*)-3,4-dicarboxyphenylglycine (DCPG), and antagonist (*RS*)-α-methyl-3,4-dicarboxyphenylglycine (MDCPG), have been described in the rat spinal cord (Thomas *et al*., 2001).
Here, we sought to further characterise the effects of these compounds in the lateral perforant path (LPP) input to the dentate gyrus, a hippocampal pathway known to express high levels of mGluR8. For comparison, DCPG effects were also studied in the medial perforant path (MPP), where group II mGluRs are thought to play a more prominent role in regulating transmission.

Using field recordings in rat hippocampal slices, we found that DCPG induced a dose-dependent reduction in the amplitude of field excitatory postsynaptic potentials (fEPSPs) in the LPP, consistent with the known role of mGluR8 as a presynaptic autoreceptor. Interestingly, the concentration-response curve was biphasic, with EC_{50} values of 0.2µM and 12.4µM for the high and low affinity components, respectively. 30µM MDCPG antagonised the high affinity component of the curve only, having no effect on DCPG concentrations >3µM. These higher concentrations of DCPG also reduced fEPSPs in the MPP, producing a curve with an EC_{50} value of 15.4µM.
Further experiments using hippocampal slices from mGluR4, 7 and 8 knock-out ($^{-/-}$) mice revealed that only the high affinity component of the curve in the LPP is mediated by mGluR8, whilst the low affinity component is non-selective and does not appear to be mediated by a group III mGluR. Instead, preliminary experiments with mGluR2$^{-/-}$ animals suggest that DCPG may activate this group II mGluR at higher concentrations, consistent with the reduction of excitatory transmission observed in the MPP at these concentrations. These findings indicate that whilst MDCPG, and lower concentrations of DCPG (<3µM) may prove useful in determining the functional role of mGluR8 in the hippocampus, care must be taken when employing higher concentrations of the agonist which may additionally be activating group II mGluRs.

Title: DHPG-induced long-term depression and E-S potentiation in transgenic mice lacking mGluR1 or mGluR5

Authors: *P. TIDBALL[1], A. VOLIANSKIS[1], S. M. FITZJOHN[2], G. L. COLLINGRIDGE[1]
[1]Physiol. & Pharmacol., Univ. of Bristol, Bristol, United Kingdom; [2]Lilly UK, Windlesham, United Kingdom

Abstract: Activation of group I metabotropic glutamate receptors (mGluRs, comprising mGluR1 and mGluR5) by the agonist (RS)-3,5-dihydroxyphenylglycine (DHPG) induces long-term depression (LTD) of glutamatergic transmission in the CA1 region of the rodent

hippocampus. Although some of the key signaling cascades involved in DHPG-LTD have been identified, precise mechanisms remain elusive with conflicting results being reported. In addition to LTD, DHPG application in hippocampal slice preparations can induce long-lasting changes in various measures of neuronal excitability, including the prolongation of epileptiform bursts and a potentiation of EPSP-spike coupling (E-S potentiation). Using transgenic mice lacking mGluR1 or mGluR5, the aim of the present study was to assess the role of these two receptors in the induction of DHPG-LTD and DHPG-induced E-S potentiation. Experiments were performed on parasagittal hippocampal slices (with the CA3 region removed) from knockout mice lacking either mGluR1 or mGluR5 or from age-matched wild-type littermates (both male and female mice were used; age range: 3 - 18 weeks). The GABAA receptor antagonist picrotoxin and the NMDA receptor antagonist L-689,560 were present in the perfusate throughout all experiments. Field EPSPs were recorded from CA1 stratum radiatum in response to Schaffer collateral stimulation and EPSP-spike (E-S) coupling was examined by simultaneously recording population spikes from the stratum pyrimadale and constructing input-output curves. In slices from wild-type mice, a 10 minute application of 100 µM DHPG induced LTD of f-EPSPs recorded in the stratum radiatum and a long-lasting potentiation of E-S coupling (LTD and E-S potentiation were assessed 40-60 minutes after DHPG washout). LTD was absent or reduced in slices from both mGluR1 and mGluR5 knockout mice. Conversely, E-S potentiation was preserved in slices from mGluR1 knockout mice, but absent in slices from mGluR5 knockout mice. These results indicate that activation of both mGluR1 and mGluR5 is required for the full induction of DHPG-LTD, whereas activation of mGuR5 alone is sufficient for the induction of DHPG-mediated E-S potentiation.

Title: Optical control of metabotropic glutamate receptors for high resolution probing of gpcr signaling

Authors: *J. LEVITZ[1], C. PANTOJA[1], B. GAUB[1], H. JANOVJAK[2], P. STAWSKI[3], D. TRAUNER[3], E. ISACOFF[1]

Abstract: G-protein coupled receptors (GPCRs) are the largest family of membrane signaling proteins and the most common drug targets in biology. They respond to a wide-array of stimuli and contain a seven transmembrane domain that couples to G-protein signaling pathways. These pathways control second messenger levels and regulate other signaling proteins, such as ion channels and kinases. Despite the importance of these receptors, specific biochemical,physiological, and behavioral roles of many GPCRs are not well-understood. In order to overcome the limitations of classical pharmacological and genetic techniques, we have developed an approach to elucidate the function of Class C GPCRs by chemically re-engineering them to be light sensitive. The group II metabotropic glutamate receptor, mGluR2, which couples to the Gi/o pathway, was derivatized with photoswitchable ligands to generate both light-agonized (LimGluR2) and light-antagonized ("LimGluR2-block") receptors. LimGluR2 activates and deactivates quickly, shows bistability which allows the receptor to remain on or blocked for extended periods in the dark, and supports multiple reproducible rounds of on/off switching with superior fidelity and speed compared to Rhodopsin. In neurons, LimGluR2 is a powerful tool for optical inhibition through hyperpolarization and presynaptic inhibition of neurotransmitter release. Furthermore, we have demonstrated that these tools function in intact hippocampal slices and in vivo, in zebrafish, to control vertebrate behavior. Recently, we have extended optical control to a variety of mGluRs with distinct G-protein coupling profiles. These designed receptors provide excellent tools for the dissection of the specific roles of different mGluRs in physiological functions with high spatiotemporal precision and subtype specificity that is lacking with traditional ligands. In addition the high resolution control of ligand-binding allows these tools to be excellent biophysical probes of receptor cooperativity and activation mechanism. Finally, future experiments aim to probe the mechanism and behavioral role of mGluR-mediated plasticity in rodents using virus delivery and knock-in mice.

Title: Influence of the group II metabotropic glutamate receptor antagonist LY341495 on nicotine sensitization

Authors: *K. TAM[1], W. HUANG[1], M. E. HEFFERNAN[1], S. M. CZERNIAK[1], J. R. DIFRANZA[2], J. A. KING*[1]
[1]Psychiatry/CCNI, [2]Family Med. & Community Health/Psychiatry, Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: The increase in dopamine transmission observed after the administration of nicotine has been supported in numerous studies. Though this neurotransmitter is a vital component of nicotine's addictive properties, recent work has also focused on glutamate, a major excitatory neurotransmitter in the brain, and its role in the neurobiology of nicotine dependence. Glutamate transmission is mediated by ionotropic and metabotropic receptors located both presynaptically and postsynaptically. Of interest to this study are the group II receptors (mGlu2/3) that inhibit glutamate release. By blocking these receptors, glutamate transmission would presumably increase, which would subsequently lead to increased dopamine transmission. A novel group II metabotropic glutamate receptor antagonist LY341495, (2*S*)-2-amino-2-[(1*S*,2*S*)-2-carboxycycloprop-1-yl]-3-(xanth-9-yl)propionic acid, has been used to explore glutamate's potential role in nicotine dependence.
In the present study, both a behavioral assay (open-field test) and neuroimaging (fMRI) were used to study the effects of LY341495 on nicotine sensitization. Male Sprague-Dawley rats were administered nicotine (0.4 mg/kg per day) for 7 consecutive days to induce sensitization, and their locomotor activity was immediately recorded. The treatment group received LY341495 thirty minutes prior to nicotine administration, while the controls received a mock injection, on Days 6 and 7. We hypothesized that LY341495 would increase locomotor activity, via an increase in glutamate transmission. Unexpectedly, our results supported a decrease in locomotor activity in the treatment group compared to controls on Days 6 and 7.
Within group analysis of fMRI results after the administration of nicotine, in LY341495 pre-treated rats, reveal strengthened connectivity between the anterior cingulate area (ACA) and the agranular insular area, hypothalamus, and hippocampus. Additionally, the lateral orbitofrontal cortex (ORBl) showed increased connectivity to the retrosplenial area and the hippocampus. Results from the behavioral assay and imaging suggest that while LY341495 appears to attenuate the nicotine-induced increase in locomotor activity, it strengthens the connectivity to brain regions associated with memory and reward. These findings support the notion that glutamate's role in nicotine dependence is complex, and glutamatergic interventions can result in different behavioral and neurobiological effects.

Title: Safety, pharmacokinetic and pharmacodynamic profile of BCI-632, a selective metabotropic glutamate 2/3 receptor antagonist, in healthy human subjects

Authors: *R. A. GADIENT[1], P. C. WEDEL[1], V. M. FRISBIE[1], A. F. LEUCHTER[2], S. D. TARGUM[1], C. T. TRUONG[1], J. H. HUTCHINSON[1]
[1]Brain Cells Inc., San Diego, CA; [2]UCLA, Los Angeles, CA

Abstract: Treatment resistant depression (TRD) is defined as the failure to fully respond to an antidepressant treatment despite having had an adequate dose and duration of treatment. There is an unmet need to develop medications to effectively treat TRD. The finding that a single administration of a sub-anesthetic dose of ketamine can lead to rapid and long lasting efficacy in TRD patients has strongly influenced depression research. The mechanism by which ketamine confers this activity has been studied by several groups. It seems to involve a burst in synaptic glutamate followed by potentiation of post-synaptic AMPA receptors, increased brain derived neurotrophic factor (BDNF) signaling and downstream activation of mTOR, leading to increased synaptogenesis. An identical signaling cascade is triggered by selective antagonists of the metabotropic glutamate receptor (mGlu) 2/3, such as LY341495 or BCI-632.
Here we report Phase 1 data for BCI-838, the oral prodrug of BCI-632, dosed to healthy male and female subjects in 2 studies: a single ascending dose (SAD) and a multiple ascending dose (MAD) study. In both, safety and tolerability were monitored and plasma was collected for pharmacokinetic (PK) analysis. In the MAD study, electroencephalograms (EEGs) were collected to assess pharmacodynamic (PD) effects on the central nervous system. In the SAD study (n=25), single doses of BCI-838 up to 900 mg were given under fasted conditions. BCI-838 was well tolerated. PK analysis revealed dose-dependent increases in BCI-632 and BCI-838 plasma levels which were slightly less than dose proportional. A food effect sub-study was included in the SAD protocol which showed an increase in BCI-632 plasma levels when BCI-838 was dosed with food. In the MAD study (n=30), BCI-838 was given under fed conditions for

7 days at doses up to 600 mg QD. At 100 and 300 mg, BCI-838 was safe and well tolerated. At 600 mg, a dose well above the estimated therapeutic range, an increase in drug-related AEs of mild to moderate severity was noted. PD analysis of the qEEG data indicates dose-dependent effects on the EEG signal indicating brain penetration. In summary, the compelling clinical data obtained for BCI-838 support the compound's progression into a proof-of-concept study in TRD patients.

Title: Analgesic activity of ceftriaxone in humans

Authors: A. MACALUSO[1], M. BERNABUCCI[2], A. TRABUCCO[2], L. CIOLLI[1], *R. GRADINI[1,2], G. BATTAGLIA[2], F. NICOLETTI[1,2], F. TROISI[1], S. COLLINI[1]
[1]Univ. Sapienza, Roma, Italy; [2]I.R.C.C.S. Neuromed, Pozzilli (IS), Italy

Abstract: We examined the analgesic action of the antibiotic, ceftriaxone, in 43 patients with carpal tunnel syndrome who underwent surgical release of the carpal tunnel ligament under local anesthesia. Two additional patients underwent surgery for ulnar neuropathy. Two groups of fifteen patients received i.m. injection of ceftriaxone (2 g) or cefazoline (1 g) prior to surgery. An additional group of patients served as control. Mechanical allodynia was assessed with the Von Frey filaments prior to, and 6 hours after drug injection. Pain thresholds were unchanged in control patients and in the group of patients receiving cefazoline. In contrast, treatment with ceftriaxone caused analgesia in all patients. Ceftriaxone is known to up-regulate the glial glutamate transporter, GLT-1 (EAAT2), in the spinal cord, a mechanism that was demonstrated in animal models of chronic pain following repeated doses of ceftriaxone. Using different mouse models of inflammatory and post-surgical pain, we have shown that a single injection of ceftriaxone was able to induce GLT-1 expression in the dorsal horns of the spinal cord after 6 hours, whereas cefazoline was inactive. In all these models, a single injection of ceftriaxone

caused analgesia and its effect was additive to that produced by the mGlu5 receptor antagonist, MPEP. Thus, a combination of ceftriaxone and mGlu5 receptor blockade might be valuable in the treatment of acute and chronic pain. These data encourage the use of ceftriaxone in surgical prophylaxis in order to combine antimicrobical and analgesic activities with the same drug. It will be interesting to examine the action of ceftriaxone combined with mGlu5 receptor antagonists in patients with severe pain refractory to conventional medications.

Abstract: The type 2 ryanodine receptor/calcium release channel (RyR2), required for excitation-contraction coupling in the heart, is the major isoform in the brain. Chronic stress induces catecholamine biosynthesis and release, stimulating β-adrenergic receptors and activating cAMP signaling pathways in neurons. In a murine chronic restraint stress model neuronal RyR2 were phosphorylated by protein kinase A (PKA), resulting in dissociation of the stabilizing subunit calstabin2 (FKBP12.6) from the channel macromolecular complex, and intracellular ER calcium leak. Chronic restraint stress impaired learning and memory, increased anxiety and reduced spontaneous exploratory activity, and decreased long-term potentiation (LTP) at the hippocampal CA3-CA1 connection. Stress-induced cognitive dysfunction and impaired post-synaptic plasticity of hippocampal neuron were rescued by oral administration of S107, a novel compound developed in our laboratory that stabilizes RyR2-calstabin2 interaction,

or by genetic ablation of the RyR2 PKA phosphorylation site at serine 2808. Thus, RyR2 remodeling in hippocampal neuron contributes to stress-induced cognitive dysfunction. Leaky RyR2 could be a therapeutic target for treatment of stress-induced cognitive dysfunction and post-traumatic stress disorder (PTSD).

Title: Acidic store-operated calcium entry in primary cultured neurons

Authors: *L. HUI[1], X. CHEN[1], B. SINGH[2], J. GEIGER[1]
[1]Pharmacol. Dep., [2]Biochem. Dep., Univ. of North Dakota, GRAND FORKS, ND

Abstract: Endolysosomes are intracellular ‘acidic’ calcium stores that contain high concentrations of readily releasable calcium. Although ‘acidic calcium stores’ are present functionally in neurons, little is known about how calcium is released from the acidic stores and how this release contributes to calcium signals both spatially and temporally. In primary cultured hippocampal neurons, we found that calcium released from acidic calcium stores triggered

calcium influx across the plasma membrane, a phenomenon we termed ‘acidic store-operated calcium entry’ (aSOCE). Because so little is know about how acidic calcium stores communicate with plasma membrane calcium channels, we tested here the hypothesis that calcium released from acidic calcium stores increases calcium influx through plasma membrane N-type calcium channels using a variety of methods including calcium imaging, electrophysiology, surface protein labeling, immunoprecipitation, and RNA interference. Similar to classical thapsigargin-induced store-operated calcium entry (SOCE), calcium released from acidic calcium stores, as induced by either inhibition of vacuolar H+-ATPase with bafilomycin or selective disruption of endolysosome membranes with GPN, triggered a dramatic influx of extracellular calcium. This aSOCE was attenuated significantly by blocking N-type calcium channels. Consistent with our calcium imaging data, our electrophysiological data demonstrated that both bafilomycin and GPN increased voltage-gated calcium currents. Biochemically, we demonstrated that bafilomycin and GPN both increased cell surface expression of N-type calcium channel and LAMP1, a lysosome associated membrane protein that plays an important role in lysosomal exocytosis. Furthermore, we observed a physical linkage between LAMP1 and N-type calcium channels. In addition, knocking down either LAMP1 or N-type calcium channels with RNA interference attenuated bafilomycin- or GPN- induced aSOCE. Collectively, our findings suggest that exocytotic insertion of N-type calcium channels might underlie this novel process of aSOCE in neurons. Such findings could provide a new insight into the spatiotemporal complexity of calcium signals and fundamental calcium-dependent cellular processes in neurons.

Title: Acute application of retinoic acid to neurons *in vitro* results in hyperpolarization of the current-voltage relationship of voltage-gated calcium channels

Authors: *T. F. DAWSON, N. D. VESPRINI, G. E. SPENCER
Biol. Sci., Brock Univ., St. Catharines, ON, Canada

Abstract: Spontaneous neuronal firing is known to be critically involved in the processes of neuritogenesis and axonal pathfinding, and both waveform and frequency of firing can be

manipulated pharmacologically. Retinoic acid (RA), a metabolite of dietary vitamin A, can cause a significant change in neuronal firing properties following acute application to cultured neurons. In addition, it has been shown that RA can influence neural development and regeneration in vertebrates through its roles in patterning, axonal pathfinding and neuritogenesis. The classical role of RA in the nucleus has been well studied, and it is known that RA binds to nuclear receptors, which then act as transcription factors. Our laboratory has demonstrated a variety of novel, non-nuclear roles for RA during the regeneration of central neurons *in vitro*. These include actions as a chemoattractant during axonal pathfinding and as a modulator of neuronal firing properties. Prior studies have shown RA's ability to induce positive growth cone turning in cultured neurons and neurites isolated from the soma. Intriguingly, the aforementioned growth cone turning corresponds temporally to the observed changes in the shape of the action potential and firing frequency induced by the acute application of RA. Specifically, RA can convert tonic firing into bursting behaviour in cultured neurons in as few as 15 minutes after application, followed by a transient period of electrical quiescence approximately 50 minutes post-application. The molecular mechanisms that underlie the electrophysiological effects of RA currently remain unknown, and so we have employed whole-cell voltage clamp to determine which ion channel(s) might be modulated by RA. It is hypothesized that RA modulates voltage-gated calcium channels (VGCCs), since it is known to alter the intracellular Ca^{2+} concentration of these neurons. Preliminary recordings of VGCCs from cultured neurons suggest that acute application of RA can transiently hyperpolarize the current-voltage relationship, potentially leading to the previously observed increase in firing probability and bursting behaviour. However, by 50 minutes the current-voltage relationship becomes depolarized, perhaps explaining the observed electrical silencing that was previously noted. Future studies will aim to determine if RA affects inactivation kinetics of VGCCs, as well as to decipher the roles of individual VGCC isoforms and retinoid receptors in the above phenomena.

Title: Ethanol-induced loss of consciousness is modulated by Cav3.1 channels in Medialdorsal Thalamic nucleus

Authors: *C.-F. V. LATCHOUMANE, S.-W. KIM, H.-S. SHIN
center for neural science, Kist, Seoul, Korea, Republic of

Abstract: The thalamus is known to play a central role in the modulation of cortical states, hence affecting perception, learning, cognition and up to consciousness states. We induced loss of consciousness using acute sedative dose of ethanol (3.0g/kg, 4.0g/kg) monitoring mice state changes in a forced walking task. General knock out Cav3.1 -/- mice and mediodorsal thalamus (MD) knock-down Cav3.1 -/- mice showed resistance to ethanol sedation and particularly a significant decreased in duration of loss of motion after 3.0g/kg injection of ethanol. The unconscious state of the mice was accompanied with increase low frequency (4-5Hz) quasi periodical EEG signal. Cav3.1 Knock out and MD knock-down mice exhibited lower delta (1-4Hz) and theta (4-8Hz) power, and higher alpha (8-12Hz) power during the unconscious phase. Our results suggest that tonic firing mode in absence of Cav3.1 mediated burst in MD can promote resistance to ethanol-induced loss of consciousness.

Title: T-type calcium channel upregulation by insulin may involve increased recycling.

Authors: *A. TOLEDO GONZÁLEZ
Biología Celular, CINVESTAV, México, DF, Mexico

Abstract: Growth factors and hormones have both short- and long-term regulatory effects on the functional expression of voltage gated calcium (Cav) channels. In particular, chronic treatment with insulin upregulates T-type channel membrane expression, leading to an increase in current density in clonal pituitary GH3 cells. Though this action may result from alterations in gene expression, recent studies have demonstrated also that endosomal trafficking provides a mechanism for dynamic changes in Cav channel membrane density. Therefore, in the present work we sought to determine whether the actions of insulin on T-channel functional expression

are mediated by transcriptional and/or post-transcriptional mechanisms. Using real-time RT-PCR and semi-quantitative Western blot we found no changes after treatment in the transcript and protein levels of Cav3.1, the T-channel isoform preferentially expressed in the GH3 cells. Consistent with this, transcriptional studies using a luciferase reporter system suggested that insulin treatment does not affect the Cav3.1 promoter activity. In contrast, patch-clamp recordings on HEK-293 cells stably expressing Cav3.1 channels showed a significant increase in current density after treatment, suggesting that the effects of insulin may require a post-transcriptional regulation. In line with this, disruption of the endosomal recycling pathway using Brefeldin A and a dominant negative mutant of the small GTPase Rab11 prevented the stimulatory effects of insulin on Cav3.1 channels in HEK-293 cells. These results may help explain the effects of insulin on T-channels and contribute to our understanding of how endosomal recycling impacts the functional expression of Cav channels.

Title: High-speed visualization of calcium mediated sub-threshold oscillations in the parafascicular nucleus

Authors: *J. R. HYDE[1], F. J. URBANO[2], E. GARCIA-RILL[1]
[1]The Ctr. for Translational Neurosci., Univ. of Arkansas For Med. Sci., Little Rock, AR; [2]IFIBYNE-CONICET, Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: The parafascicular nucleus (Pf) is an ascending target of the pedunculopontine nucleus (PPN) and is part of the “non-specific” intralaminar thalamus modulating arousal. The PPN is involved in waking and REM sleep. Cortical EEG during these periods shows gamma band activity (~30-80Hz). In vitro, gamma oscillations are evident in all Pf neurons and are mediated by high threshold voltage-dependent P/Q- and N- type calcium channels. These studies tested the hypothesis that calcium sensitive dyes can be used to visualize sub-threshold calcium oscillations and that these visual recordings match electrical oscillations recorded using whole cell patch clamp.
Electrical responses were recorded using whole cell patch clamp electrodes using 9-18 day old sagittal rat brain slices. Slices were recorded at 37°C while perfused with oxygenated aCSF in an immersion chamber containing synaptic blockers: APV, CNQX, Gabazine, Strychnine, and Tetrodotoxin. Recording electrodes also contained Fura-2, Indo-1, or Fluo-4 calcium sensitive dye. Cadmium was added to the aCSF to block voltage sensitive calcium channels as a control. The dendrites were visualized using a high speed, dual camera imaging system (Evolve 128, Photometrics).
Calcium-mediated imaging recordings in the proximal dendrites showed a marked increase in activity as Pf neurons were depolarized using ramps. This occurred using all fluorescent calcium labels. Spectral power analysis of the electrical and calcium recordings showed time-coinciding peaks in both signals. The increase in calcium signal and the ramp-induced oscillations disappeared with the addition of cadmium. Cadmium also abolished the peaks in both the power spectra of both signals.
Overlaying calcium and electrical recordings showed highly coincident oscillation peaks. Preliminary data suggests the presence of distributed oscillatory sub-domains. Each domain oscillates with a local phase and timing while the oscillations seen in electrical recordings in the soma are an average of the activity in all sub-domains. This study shows that high-speed calcium imaging is a viable method for measuring sub-threshold calcium oscillations with high spatial and temporal resolution.

Title: The effects of Conus striatus venom on the T-type calcium channel ($Ca_v3.2$)

Authors: G. FROST[1], M. WEAVER[1], *L. B. FRENCH[2]
[1]Neurosci., [2]Allegheny Col., MEADVILLE, PA

Abstract: The low voltage activated T-type calcium channel**,** $Ca_V3.2$, has been implicated in the progression of prostate cancer towards an androgen independent stage (AI), for which there is no effective treatment. Calcium influx through this channel stimulates the synthesis and secretion of mitogenic factors that cause cell proliferation in adjacent cells. Therefore, finding a specific inhibitor of the $Ca_V3.2$ channel could potentially prevent the uncontrolled proliferation of prostate cells that characterizes the AI stage of prostate cancer. *Xenopus laevis* oocytes expressing this channel were exposed to crude *Conus striatus* venom, and the current through these channels before and after exposure was monitored by two-electrode voltage clamp. *Conus striatus* is a species of predatory marine snails whose venom contains a cocktail of peptides that target ion channels, known as conotoxins. Exposure to the crude venom significantly ($p<0.05$) decreased current through the $Ca_V3.2$ channel indicating inhibition. The venom was separated into components by HPLC and the effect of the fractions was tested to identify the specific conotoxin responsible for decreasing calcium current. The active component of the venom was successfully narrowed down to 1 of 6 venom components. However, further investigation is required to isolate the specific $Ca_V3.2$ channel antagonist.

Abstract: The continued concernment resting on the heterogeneity of hippocampal rhythmic oscillatory activities at theta frequency (4-12Hz) is due to their implication in diverse brain functions. However, the underlying neural mechanism for behavioral basis of hippocampal theta oscillations remains unclear. Here we provide the evidence for the functional role of Cav3.1 T-type calcium channel in modulating hippocampal theta oscillations and novel objects exploration behavior. We found that mice with a null mutation for the Cav3.1 channels (Cav3.1-/- mice) showed increased theta power under urethane anesthesia (atropine-sensitive type-2 theta rhythm) and also during wheel running (atropine-resistant type-1 theta rhythm) . Interestingly, Cav3.1-/- mice showed enhanced response to novel objects behavior, increased locomotor activity and alleviated anxiety. To verify the connection between Cav3.1 channels highly expressed in the medial septum and these diverse behaviors, we specifically knock down the endogenous Cav3.1 expression in medial septal neurons by Lentiviruses-mediated RNAi. The mice with selectively reduced Cav3.1 expression (shCav3.1) in the medial septal neurons show increased type 2 theta power without any change in the type1 theta power. Also these mice showed enhanced response to novel objects behavior similar to that of Cav3.1-/- mice with no change in locomotor activity and anxiety behavior. There was a strong correlation between type-2 theta power and enhanced novelty behavior observed for shRNA control mice and shCav3.1 mice. Cav3.1 channels in the medial septum are strongly expressed in the septo-hippocampal GABAergic neurons which are known to modulate the amplitude of type-2 theta rhythm. We found that the septo-hippocampal GABAergic neurons without Cav3.1 channels in the mutant mice showed marked increased discharge activity which explains the increased type-2 theta rhythm via the disinhibition of hippocampal local GABAergic neurons. Taken together, these findings suggest that Cav3.1 T-type calcium channel in the medial septum is critically involved in controlling the hippocampal type 2 theta oscillations and enhanced novelty behavior.

Title: Cav 3.2 T-type channels are up-regulated by chronic hypoxia: Involvement in pain signaling pathways

Authors: *C. CALORIO[1], V. COMUNANZA[2], A. MARCANTONI[1], S. MARCHIO[2], F. BUSSOLINO[2], E. CARBONE[1]
[1]Univ. of Torino, Dept of Neuroscience, NIS Ctr. of Excellence, CNISM, INN, Torino, Italy; [2]Inst. for Cancer Res. and Treatment, Candiolo, Turin, Italy

Abstract: T-type calcium channels (TTCCs) are well established mediators of pain signals in primary afferent neurons (DRG neurons). Recent studies indicate that in parallel with the development of diabetes-induced pain, T-type current density increase by twofold in medium-size cells from DRG neurons (Jagodic et al., 2007, J Neurosci, 27:3305).
Moreover, the hyperexcitability of peripheral nerves observed during diabetic neuropathies is associated with a decrease of blood flow that leads to nerve hypoxia (Chavez et al., 2005, Neurosci Lett, 374:179).This issue is of particular interest since chronic hypoxia (CH) up-regulates Cav3.2 TTCCs both in adrenal chromaffin cells (Carabelli et al., 2007, J Physiol, 584:149-65) and PC12 cells .
Furthermore, chronic responses to hypoxia are regulated by the hypoxia- inducible transcription factors (HIFs), whose accumulation is mediated by a ROS-dependent Ca^{2+}-signaling pathway (Yuan et al, 2008, J Cell Physiol, 217 :674).
Here, by combining immunostaining and electrophysiological recordings we show that CH (15 h, 3% O_2) up-regulates TTCCs in small DRG neurons via the HIF-1alpha pathway.
We found that CH significantly increases the percentage of cells expressing TTCCs (from 66 to 84%) while the T-type current density increases by a factor two in hypoxic small DRG neurons, but not in medium-size DRGs. The pharmacological and kinetics properties of CH-up-regulated currents did not change substantially, suggesting a selective up-regulation of the same Cav3.2 subunit available at control. Interestingly,

CH potentiates also DRG excitability manifested by a more prominent after depolarizing potential (ADPs) phase (from 9% to 24%) during the repolarization phase of evoked action potentials.
Voltage-clamp
recordings showed that the up-regulatory effects of CH on TTCCs are mimicked by overnight incubation with the iron chelating agent deferoxamine (DFX), which activates HIFs, while immunostaining revealed an enhanced expression of HIF-1alpha in small-size DRG neurons following CH. These data strongly suggest the involvement of HIF-1alpha in TTCCs up-regulation. Finally, we found that TTCCs recruitment occurred as
a results of ROS generation and PKC/IP_3 pathway activation.
Our data reinforce the idea that
TTCCs are pro-nociceptive and can be recognized as potential therapeutic targets for the treatment of chronic pain associated with CH.

Title: Rapid inhibition of voltage-dependent calcium and sodium currents by estrogen receptor agonists in rat basal forebrain cholinergic neurons

Authors: *D. W. DUBOIS, D. MURCHISON, A. S. FINCHER, B. ASWIN, K. A. PEEBLES, W. H. GRIFFITH
Dept. of Neurosci. and Exptl. Therapeut., Texas A&M Univ. Hlth. Sci. Ctr., Bryan, TX

Abstract: Estrogen receptors on the plasma membrane mediate a variety of molecular signaling events in many cell types. In neurons, estrogenic signaling can rapidly enhance or inhibit synaptic transmission and voltage-gated channel function, depending on brain region. Previously, we reported that 17β-estradiol (17βE) and other estrogen receptor agonists, potently reduced spontaneous frequency of IPSCs in rat basal forebrain (BF) cholinergic neurons, and that this inhibition was reduced in middle-aged males and reproductively senescent (acyclic) females.

These results implicated at least two classes of receptor in this rapid estrogenic modulation: first, the G-protein coupled estrogen receptor (GPER) and second, the estrogen receptor beta (ERβ) located on the plasma membrane. Membrane-delimited (non-nuclear) classical estrogen receptors are thought to exert their rapid effects by direct or indirect coupling to G-protein cascades. The purpose of this study is to test the hypothesis that estrogen receptor agonists rapidly modulate voltage-gated channel function in BF neurons. We used conventional whole-cell patch clamp recording in acutely dissociated BF neurons from both male and female rats (2-4 months). Cholinergic neurons (choline acetyl-transferase positive) were identified by single-cell RT-PCR. In preliminary studies, high voltage-activated (HVA) Ca^{2+} currents in Sprague-Dawley rats were sensitive to17βE (100 nM) with 57% inhibition (12 of 12 cells) and 21% inhibition by the GPER agonist G-1 (100 nM, 4 of 4 cells). Low voltage-activated (LVA) Ca^{2+} currents also were reduced 34% by 17βE (11 of 13 cells) and 20% inhibited by G-1 (4 of 5 cells). In identified cholinergic neurons from F344 rats, in males, HVA currents were inhibited 24% by 100 nM 17βE (5 of 6 cells) and in females by 42% (3 of 3 cells). LVA currents were inhibited by 24% in males (3 of 5) and 19% in females (2 of 4). The estrogen receptor agonists (100 nM) PPT (ERα agonist) and DPN (ERβ) had little effect. DPN modulated HVA currents by < 5% in both males (n=4) and females (n=3). PPT inhibited HVA currents by < 10% in 6 of 7 cells in both sexes. Voltage-gated Na^{+} currents were inhibited 13% by 100 nM 17βE (5 of 5 cells) and 24% by 500 nM (9 of 13 cells). G-1 (100nM) inhibited Na^{+} currents by 17% (7 of 10). In mature adult females (9-10 months), Na^{+} currents were inhibited 21% by 17βE 500 nM (4 of 5 cells). Experiments are in progress to complete this pharmacological profile and extend this investigation to reproductively senescent females. These results support the interpretation that rapid estrogenic modulation of function in rat cholinergic BF neurons has GPER inhibition of voltage-gated channels as a major component.

Title: Characterization of Ca2+-Binding Protein 1 (CaBP1) expression and localization in mouse brain

Authors: *K. Y. KIM[1], A. SHEPHERD[2], X. LIU[1], F. HAESELEER[3], A. LEE[1]
[1]Mol. Physiol. and Biophysics, [2]Pharmacol., Univ. of Iowa, Iowa City, IA; [3]Physiol. & Biophysics, Univ. of Washington, Seattle, WA

Abstract: CaBP1 is a calmodulin-like Ca2+ binding protein that may regulate neuronal functions through interactions with effectors including intracellular and plasma membrane Ca2+ channels. Multiple variants of CaBP1 have been characterized (CaBP1S, CaBP1L, and caldendrin), but little is known about their roles in specific neurological contexts. To gain insights into the cellular functions of CaBP1, we characterized the expression and localization of CaBP1 variants in mouse brain. Although all CaBP1 variants were amplified by RT-PCR, caldendrin, but little CaBP1S or CaBP1L, was detected in western blot analysis of mouse brain lysates with antibodies recognizing all 3 variants. Two isoforms of caldendrin were found (33 and 36 kDa), which were consistent in size with translation from alternative start sites within a single transcript. The western blotting results reflected the expression of CaBP1/caldendrin since they were not reproduced in mice with targeted disruption of the gene encoding CaBP1/caldendrin (CaBP1 KO). By immunoperoxidase labeling, CaBP1/caldendrin was localized in multiple cell-types including pyramidal cells in the cerebral cortex and hippocampal CA3 region and interneurons in the cerebellum of wild-type but not CaBP1 KO mice. Double-labeling indicated that CaBP1/caldendrin was localized in parvalbumin-positive interneurons in the cerebral cortex and cerebellum. CaBP1/caldendrin was not detected in cerebellar Purkinje neurons but strongly colocalized with GAD65 in pinceaux synapses formed between basket cells and the Purkinje cell axon initial segment. We conclude that caldendrin is the dominant CaBP1 variant expressed in mouse brain. Moreover, CaBP1/caldendrin is localized both pre- and post-synaptically and is positioned to regulate both excitatory and inhibitory transmission.

Title: Harmaline attenuates voltage-sensitive Ca^{++} currents in inferior olive neurons

Authors: *X. ZHAN[1,2], W. M. GRAF[1]
[1]Dept. Physiol. & Biophysics, Howard Univ. Coll. Med., WASHINGTON, DC; [2]Dept. Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Harmaline is a tremor-inducing alkaloid which has been reported to interact with several neurotransmitter receptors as well as ion exchangers and voltage-sensitive channels. One site of harmaline action in the brain is the inferior olive. Either local or systemic harmaline application increases action potential firing rates in the inferior olive and this activation is thought to produce tremor and ataxia through activation of target neurons in the cerebellum. We have performed whole cell voltage-clamp and current clamp recordings from inferior olive neurons in brain slices derived from young rats. We found that transient low-voltage activated (LVA) and sustained high voltage-activated (HVA) Ca^{++} currents are significantly attenuated by 125 - 250 μM harmaline applied to the bath and that this attenuation is partially reversible. In current clamp recordings, action potential after-hyperpolarization complexes were evoked by brief positive current injections. Harmaline produced a small attenuation of action potential amplitudes, but also large action potential broadening associated with attenuation of the fast and medium after-hyperpolarization. Our data suggest that one mode of inferior olive activation by harmaline may involve attenuation of both LVA and HVA Ca^{++} conductances with subsequent attenuation of Ca^{++}-sensitive K^{+} conductances resulting in spike broadening and attenuation of the after-hyperpolarization.

Title: Expressional and functional analysis of N-type calcium channel in the hippocampus using Cacna1b gene knockout mice

Authors: *N. MIYAMOTO, C. M. NAKAZAWA
EISAI Co., Ltd., TSUKUBA, Japan

Abstract: Voltage-gated Ca^{2+} channels (VGCCs) are essential for a wide variety of physiological functions including neural degeneration and hippocampal synaptic plasticity. Chronic hypertension is associated with an increased risk of both vascular dementia and Alzheimer's diseases. Anti-hypertensive dihydropyridin-calcium channel blocker therapies have been associated with a beneficial effect on cognitive function by lowering blood pressure and/or by specific neuroprotect effect. Long-term effects of L-type Ca^{2+} channel blocker nitrendipine protects against dementia in older patients with systolic hypertension. Moreover, a positive effect of nimodipine in AD patients to slow cognitive decline compared to placebo in short-term trials [1]. Furthermore, peripherally and central administration of L-type Ca^{2+} channel blockers facilitate retention of passive avoidance and maze learning in mice [2]. Chronic oral treatment of verapamil in mice facilitates on short-term presynaptic plasticity of dentate gyrus cells [3]. The T-type C Ca^{2+} channel deficient mice are impaired in the context-cued trace fear conditioning, step-down and step-through passive avoidance tasks and long-term potentiation in hippocampal slices [4]. The possibility that N-type Ca^{2+} channel could contribute to synaptic plasticity in the hippocampus was examined in this study. α1 subunit of N-type Ca^{2+} channel is encoded by *Cacna1b* gene that is specifically expressed in nervous system and the gene product is predominantly coupled to the synaptic transmission. To investigate the functional role of this channel in hippocampus, we subjected *Cacna1b* gene homozygous knockout mice and their wild-type littermates to microarray data analysis. Among more than two-fold expressional changed genes in steady-state of hippocampus, greatly affected canonical biological pathways were glutamate receptor signaling, amyotrophic lateral sclerosis signaling, synaptic long-term depression, Huntington's disease signaling, calcium signaling and nitric oxide signaling in the cardiovascular system. Those data suggested that this channel could be related to learning and memory as well as other type of VGCCs. Electrophysiological experiments using mutant hippocampal slices is underway to answer the question. [1] E. Duron and O. Hanon *J. Alzheimers Dis* **20** (2010) 903-914., [2] D. Title: Modulation of N-type Ca(2+) currents by moxonidine via imidazoline I(1) receptor activation in rat superior cervical ganglion neurons

Authors: Y. KIM, D. AHN, *S. CHUNG
Physiol., Dept. of Physiology, Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Moxonidine, an imidazoline deriviatives, suppress the vasopressor sympathetic outflow to produce hypotension. This effect has been known to be mediated in part by suppressing sympathetic outflow via acting imidazoline I_1 receptors (IR_1) at postganglionic sympathetic neurons. But, the cellular mechanism of IR_1-induced inhibition of noradrenaline (NA) release is still unknown. We therefore, investigated the effect of IR_1 activation on voltage-dependent Ca^{2+} channels which is known to play an pivotal role in regulating NA in rat superior cervical ganglion (SCG) neurons, using the conventional whole-cell patch-clamp method. In the presence of rauwolscine (30μM), which blocks α_2-adrenoceptor ($R_{\alpha 2}$), moxonidine inhibited voltage-dependent Ca^{2+} current (I_{Ca}) by about 30%. This moxonidine-induced inhibition was almost completely prevented by efaroxan (10 μM) which blocks IR_1 as well as $R_{\alpha 2}$. These data suggest that moxonidine inhibit voltage-dependent N-type Ca^{2+} current (I_{Ca-N}) via activating IR_1. Finally, moxonidine significantly decreased the frequency of AP firing in a partially reversible manner. Taken together, our results suggest that activation of IR1 in SCG neurons reduced $I_{Ca\text{-}N}$ in a PTX-and voltage-insensitive pathway, and this inhibition attenuated repetitive AP firing in SCG neurons.

Title: Novel ω-conotoxins potently inhibit N-type voltage-gated calcium channels in sensory neurons and partially reverse pain behavior after systemic dosing

Authors: *M. SADEGHI[1], S. S. MURALI[2], R. J. LEWIS[3], P. F. ALEWOOD[3], M. J. CHRISTIE[2]
[1]Pharmacology, Sydney Univ., [2]Sydney Univ., Sydney, Australia; [3]UNIVERSITY OF QUEENSLAND, BRISBANE, Australia

Abstract: ω-Conotoxins, selective inhibitors of N-type voltage-gated calcium channels, have emerged as a new class of therapeutics in pain management. ω-Conotoxins are usually administered intrathecally to directly inhibit neurotransmitter release at primary afferent synapses. However, the therapeutic indices of intrathecally administered ω-conotoxins are quite narrow. It has been reported that intravenous injection of ω-conotoxin CVID, isolated from *C.catus*, produces dose-dependent antihyperalgesic effects with less serious cardiovascular side effects than those reported for some other ω-conotoxins (Kolosov et al, 2009, Pain Med 11, 262-73). In the present study we investigated the potency, voltage-dependence and reversibility of ω-conotoxins more recently isolated from *C.catus* and several analogues (Berecki et al, 2010, Mol Pharmacol 77, 139-148) in mouse isolated DRG neurons and determined whether systemic administration of these ω-conotoxins can produce inhibition of inflammatory pain behaviors.Whole-cell patch clamp electrophysiology on isolated mouse DRG neurons demonstrated that CVIE is significantly more potent than CVID, CVIE(R10K),CVIF(R10K) and CVIF. ω-conotoxins have higher affinity for the inactive state of VGCCs a strong membrane hyperpolarization facilitates recovery from block. For evaluating the pain alleviating effects of ω-conotoxin following systemic administration, we used a hindpaw inflammatory pain model (Freund's Complete Adjuvant) in mice and tested hind paw weight bearing and von Frey thresholds before and 1,2,4 and 6 hours after s.c. administration of different doses (0.02,0.2 and 2 mg/kg) of each ω-conotoxin. All peptides produced significant partial reversal of inflammatory pain at a dose of 2 mg/kg and the peak effect was observed 2 hours post-injection, with less obvious effects at lower doses. CVIE had the largest effect of all peptides at 2mg/kg but was not more potent that CVID. These findings suggest that systemically administered ω-conotoxin CVIE may be useful in pain management.

Title: A mechanism of hypotension induced imidazoline I_2 receptors activation in agmatine

Authors: S. CHUNG, *Y. KIM
physiology, Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Agmatine, an imidazoline deriviatives, suppress the vasopressor sympathetic outflow to produce hypotension. This effect has been known to be mediated in part by suppressing sympathetic outflow via acting imidazoline I_2 receptors (IR_2) at postganglionic sympathetic neurons. But, the cellular mechanism of IR_2-induced inhibition of noradrenaline (NA) release is still unknown. We therefore, investigated the effect of IR_2 activation on voltage-dependent Ca^{2+} channels which is known to play an pivotal role in regulating NA in rat superior cervical ganglion (SCG) neurons, using the conventional whole-cell patch-clamp method. In the presence of rauwolscine (30μM), which blocks α_2-adrenoceptor ($R_{\alpha 2}$), agmatine inhibited voltage-dependent Ca^{2+} current (I_{Ca}) by about 30%. This agmatine-induced inhibition was almost completely prevented by BU224 (10 μM) which blocks IR_2 as well as $R_{\alpha 2}$. These data suggest that agmatine inhibit voltage-dependent N-type Ca^{2+} current (I_{Ca-N}) via activating IR_2. Finally, agmatine significantly decreased the frequency of AP firing in a partially reversible manner. Taken together, our results suggest that activation of IR_2 in SCG neurons reduced I_{Ca-N} in a PTX- and voltage-insensitive pathway, and this inhibition attenuated repetitive AP firing in SCG neurons.

Title: Alterations in serotonergic modulation of basolateral amygdala neurons in bdnf conditional mutant mice

Authors: *S. S. DAFTARY, G. CALDERON, M. RIOS
Dept Neurosci, Tufts Univ. Sch. Med., BOSTON, MA

Abstract: $BDNF^{2L/2LCamk\text{-}cre}$ mutant mice with brain-specific deletion of the *Bdnf* gene are characterized by an increase in aggressive, anxiety and depressive-like behavior. The behavioral

alterations elicited by perturbed BDNF signaling highlight the importance of this pathway in the regulation of affective behavior. One possible mechanism by which BDNF might modulate mood is by regulating serotonergic neurotransmission in regions of the brain traditionally associated with psychiatric disorders, such as the basolateral amygdala (BLA). To investigate this, we examined whether $BDNF^{2L/2LCamk\text{-}cre}$ mutant mice exhibited alterations in 5-HT transmission in this limbic region of the brain.
Immunohistochemical studies found that BLA GABAergic and pyramidal projection neurons contain TrkB receptors, indicating their ability to be influenced by BDNF. Notably, whole cell patch-clamp recordings from BLA projection neurons in wild-type and BDNF mutants did not indicate any differences in passive membrane properties such as resting potential, input resistance, spike amplitude, spike threshold, membrane time constants and spontaneous excitatory/inhibitory postsynaptic currents under basal conditions. However, bath application of serotonin uncovered significant alterations in the modulation of GABAergic and glutamatergic synaptic transmission in BDNF mutant mice compared to wild-type mice resulting in a hyperexcitable circuit. These changes were associated with decreased expression of $5\text{-}HT_2$ receptors in the BLA. Collectively, our findings indicate that 5-HT-mediated transmission in the BLA is altered in BDNF mutants, which might contribute to the behavioral alterations that they exhibit, including increases in anxiety-like behavior.

Title: A novel role for the serotonin transporter in the regulation of neuroendocrine stimulus-secretion coupling

Authors: *R. L. BRINDLEY[1], R. D. BLAKELY[2], K. P. CURRIE[3]
[1]Dept. of Anesthesiol., Vanderbilt Univ. Med. Ctr., Nashville, TN; [2]Dept. of Pharmacol., [3]Departments of Anesthesiol. and Pharmacol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: The serotonin transporter (SERT), an important target for anti-depressants, mediates the reuptake and recycling of serotonin (5HT) from serotonergic synapses. SERT is also expressed outside the brain, including prominently in adrenal chromaffin cells. These cells are a crucial output of the sympathetic nervous system and also provide a good model for neurosecretion. They release a variety of transmitters, including epinephrine and norepinephrine, to help maintain homeostatic functions and provide appropriate responses to acute stress. Autocrine / paracrine signaling pathways tightly regulate stimulus-secretion coupling from chromaffin cells and failure to do so can contribute to the development of hypertension and heart failure. Increasing evidence links depression and cardiovascular diseases, and some depressed patients exhibit elevated catecholamine levels, perhaps suggesting common molecular targets or mechanisms. Chromaffin granules store and release 5HT, albeit at > 1000 fold lower concentration than epinephrine. However, the function of 5HT / SERT in chromaffin cells remains unclear. We postulated that 5HT is accumulated through uptake by SERT. Consistent with this, when bovine chromaffin cells were cultured in media with dialyzed fetal bovine serum (to remove extracellular 5HT) there was a dramatic reduction in intracellular 5HT, but no change in catecholamine content. Addition of 5HT to the dialyzed culture medium rescued the intracellular 5HT content and this was blocked by the SERT antagonist citalopram. Similarly, the 5HT content of adrenal glands from SERT knockout (KO) mice was dramatically reduced compared to wild type littermates with no change in catecholamine content. We used carbon fiber amperometry to investigate the effect of 5HT / SERT on secretion from mouse chromaffin cells. In the presence of extracellular 5HT, loss of SERT activity (acute block by citalopram or use of cells from SERT KO mice) reduced catecholamine secretion evoked by KCl. Whole cell patch clamp experiments showed that 5HT / citalopram did not alter voltage-gated calcium channels. Thus our data demonstrate that intracellular 5HT accumulation in chromaffin cells relies upon uptake by SERT. Loss of SERT has no effect on cellular catecholamine content, but does inhibit exocytosis. We postulate that 5HT acts at an intracellular site(s) following uptake by SERT to control exocytosis, rather than extracellularly via G protein coupled receptors. Ongoing work will investigate this novel mechanism for controlling neuroendocrine catecholamine release.

Title: Presynaptic 5-HT1B receptor-mediated synaptic suppression to the subplate neurons in the somatosensory cortex of neonatal rats

Authors: *L.-J. LEE[1,2,3], C.-C. LIAO[1]
[1]Grad. Inst. Anat. and Cell Biol., [2]Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Serotonin (5-HT) is the target of numerous psychiatric medicines and also plays important roles during neural development. To evaluate the influence of 5-HT in the developing brain, we examined the direct effects of 5-HT on the intrinsic and synaptic properties of neurons in the cortical subplate, an early developed structure that plays important roles in the consequential maturation of cortical circuits. Acute brain slices were obtained from neonatal rats and the physiological properties of SPns were evaluated before and after 5-HT bath-application. In all concentrations tested, 5-HT did not affect the intrinsic properties of SPns. However, thalamus-evoked excitatory postsynaptic currents (eEPSCs) to SPn was significantly suppressed by 5-HT in a dose-dependent manner. Because 5-HT did not affect AMPA-induced EPSC, our results did not support a 5-HT-mediated postsynaptic mechanism in reducing EPSCs. Subsequent to 5-HT application, increased paired-pulse ratio and decreased MK-801 blocking rate were noted, indicating the presence of presynaptic 5-HT receptor-mediated suppressive effect in the thalamocortical afferent (TCA)-SPn synapses. To elucidate the type(s) of 5-HT receptor involved in this process, various 5-HT receptor agonists and antagonists were tested. Our results showed that 5-HT1B receptor agonist CP93129 mimicked the effect of 5-HT and only 5-HT1B receptor antagonist SB224289 prevented 5-HT-mediated synaptic suppression. Taken together, our data demonstrated the presynaptic 5-HT1B receptor-mediated suppressive effect on the excitatory synapses between TCAs and SPns in the somatosensory cortex of neonates. Use of drugs that might interrupt 5-HT homeostasis in pregnant women should be concerned.

Title: Differential roles of 5-HT1A, 5-HT1B and 5-HT1D receptors in modulation of entorhinal-hippocampal synaptic transmission and connections: Multi-electrode array recordings

Authors: J. JIN[1], J. CHEN[3], *Q. LIN[2]
[1]Psychology, Univ. of Texas At Arlington, Arlington, TX; [2]Psychology, Univ. of Texas At Arlington, Arlington, ; [3]Inst. for Biomed. Sci. of Pain, Capital Med. Univ., Beijing, China

Abstract: The hippocampus is a major target of serotonergic afferents arising from the midbrain raphe nuclei. Serotonin (5-HT)-containing fibers project to the dorsal hippocampus innervating the CA1 and dentate gyrus (DG). The effects of 5-HT on regulation of pain, memory and depression are mediated through its 14 receptor subtypes. There exist many subtypes of 5-HT receptors in the hippocampal formation whereby 5-HT produces differential excitatory and inhibitory effects on hippocampal neurons. However, the roles of 5-HT receptors in modulation of the entorhinal-DG and entorhinal-CA1 synaptic connections at the network level have rarely been studied. Using a 64-channel multi-electrode array (Med 64 System), modulatory effects of 5-HT_{1A}, 5-HT_{1B} and 5-HT_{1D} receptors were studied on the entorhinal-hippocampal synaptic transmission and connections. We recorded two types of field excitatory postsynaptic potentials (fEPSPs) in the CA1 and DG evoked by electrical stimulation of the perforant path in hippocampal slices of rats. After stability of network fEPSPs was achieved, hippocampal slides were perfused with the agonist of 5-HT_{1A} receptors, 8-OH-DPAT, antagonist of 5-HT_{1A} receptors, WAY100635, antagonist of 5-HT_{1B}, SB224289, and antagonist of 5-HT_{1D}, BRL15572, respectively, for 15 min. Two-dimensional current source density analysis was transformed by the bilinear interpolation at each point of the 64 electrodes for spatial imaging of the network fEPSP responses. The results show that perfusion of hippocampal slices with the 5-HT_{1A} receptor antagonist resulted in significant enlargements of synaptic network connection size and synaptic efficacy. In contrast, perfusion with the 5-HT_{1A} receptor agonist produced a reversal effect with reductions in synaptic size and magnitude of fEPSPs. However, perfusion of hippocampal slices with the antagonist of 5-HT_{1B} or 5-HT_{1D} receptors resulted in significant reductions in synaptic size and synaptic efficacy. Thus, we suggest that endogenous release of 5-HT causes an inhibition of entorhinal-CA1 and entorhinal-DG synaptic transmission and connections via acting on 5-HT_{1A} receptors, whereas 5-HT_{1B} and 5-HT_{1D} receptors may mediate an opposite role in synaptic transmission and connections of the entorhinal-CA1 and entorhinal-DG.

Title: Presynaptic inhibition of glutamate release by serotonin in the lateral habenula

Authors: *E.-K. HWANG, J.-M. CHUNG
Dept. of Brain and Cognitive Sci., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: The lateral habenula nucleus (LHb), known to regulate dopamine and serotonin (5HT) systems in mammalian brain, involves in the regulation of several mental functions such as reward, stress, pain, maternal behavior and cognition. Anatomically LHb where binding sites as well as mRNAs for various 5HT receptor subtypes are present reciprocally connects with 5HT resources such as raphe nuclei, implying that synaptic responses of LHb neurons may be modulated by 5HT. In this study, we have examined, using a whole cell voltage-clamp recording, how 5HT modulates glutamatergic transmission in LHb. We observed that 5HT directly suppressed glutamatergic transmission by decreasing the probability of glutamate release from presynaptic terminals. This inhibitory action of 5HT onto CNQX-sensitive glutamatergic EPSCs was further confirmed by the applications of $5HT_{1B}$ receptor agonist and/or antagonist. The 5HT-induced suppression of glutamate release was also found to be mediated mainly by the activation of a voltage-gated K^+ channel sensitive to both 4-aminopyridine and α-dendrotoxin. Therefore, all these results indicate that 5HT reduces excitatory signals onto an LHb neuron by hyperpolarizing its presynaptic terminals through the activation of $5HT_{1B}$ receptors.

Title: Dopamine facilitates evoked excitatory synaptic currents in layer II of the lateral entorhinal cortex through D1-family receptors

Authors: *I. GLOVACI, C. A. CHAPMAN
Ctr. For Studies In Behavioral Neurobiology, Concordia Univ., Montreal, QC, Canada

Abstract: The entorhinal cortex receives dopaminergic inputs from the ventral tegmental area and substantia nigra that may modulate its responsiveness to inputs from other cortical areas. Previous research has shown that dopamine produces concentration-dependent changes in synaptic transmission in layer II neurons of the lateral entorhinal cortex, such that high concentrations of dopamine suppress evoked EPSPs, and lower concentrations of dopamine facilitate EPSPs. Our studies of the enhancement of EPSPs induced by dopamine have shown that it depends on cell type; Layer II entorhinal fan cells, characterized by a sag in the voltage response to hyperpolarizing current steps, typically show a larger dopamine-induced facilitation of mixed EPSPs evoked by layer I stimulation as compared to pyramidal and multiform cells. Presently, we have used voltage-clamp recordings of electrophysiologically differentiated fan and pyramidal neurons to investigate the underlying signalling mechanisms that mediate the dopaminergic facilitation of excitatory synaptic responses in submerged slices of the lateral entorhinal cortex. We have found that dopamine facilitates pharmacologically-isolated AMPA glutamate receptor-mediated EPSCs, but does not significantly affect pharmacologically-isolated NMDA receptor-mediated EPSCs. To determine the dopaminegic receptor subtype responsible for the facilitation of EPSCs, either the D1 receptor blocker SCH-23390 (50 µM) or the D2 receptor blocker sulpiride (50 µM) was bath applied prior to dopamine application. Application of SCH-23390 blocked the facilitation of EPSCs, whereas application of sulpiride had no significant effect on the facilitation of synaptic currents induced by dopamine. Therefore, we suggest that dopaminergic enhancement of EPSCs is likely to be mediated primarily through D1-family receptors. D1 dopamine receptors can act through a variety of intracellular signalling pathways dependent on protein kinase A to modulate synaptic strength. In the present study, we have tested the role of signalling via protein kinase A by including the PKA inhibitor H-89 in the recording pipette solution. Cells filled with H-89 did not show a significant facilitation of EPSCs in response to dopamine application. Thus, the dopamine-induced facilitation of AMPA receptor-mediated synaptic responses in layer II neurons of the lateral entorhinal cortex appears to be mediated via a D1 receptor-dependent increase in PKA activity.

Title: DIfferential noradrenergic modulation of synaptic AMPA- and NMDA-type glutamate receptors in the prefrontal cortex

Authors: G. LUR, *M. J. HIGLEY
Neurobio., Yale Sch. of Med., New Haven, CT

Abstract: Cognitive functions such as working memory and attention are strongly influenced by noradrenergic modulation of neuronal activity. Emerging evidence suggests that distinct subtypes of adrenergic receptors play differential roles in neuropsychiatric illnesses such as attention deficit and anxiety disorders. Noradrenaline (norepinephrine) is thought to regulate glutamatergic synaptic transmission in the prefrontal cortex. However, the cellular targets and mechanisms of this modulation remain poorly understood. To investigate noradrenergic modulation of excitatory synapses in the mouse prelimbic and infralimbic cortices, we first utilized afferent-specific expression of Channelrhodopsin2. Our experiments revealed that noradrenaline negatively regulates inputs to prefrontal layer 5 pyramidal neurons arising from both the ventral hippocampus and medial thalamus. We then used 2-photon laser scanning microscopy and focal 2-photon glutamate uncaging to analyse the postsynaptic actions of noradrenaline on individual dendritic spines. We stimulated glutamatergic synapses in three subcellular regions: basal dendrites, proximal apical oblique dendrites, and the apical tuft. Activation of α1 adrenergic receptors (A1Rs) had minimal effect on uncaging evoked excitatory postsynaptic potentials (uEPSPs) but significantly reduced the evoked synaptic calcium transient in all three regions. In contrast, activation of α2 receptors (A2Rs) significantly reduced both uEPSPs and calcium transients in basal dendrites and the apical tuft but had no effect in apical oblique dendrites. Subsequent experiments revealed that A1Rs specifically reduce synaptic currents and calcium influx through NMDA-type glutamate receptors, while A2Rs reduce currents through AMPA-type receptors. Our data demonstrate that noradrenergic modulation of synaptic transmission occurs via distinct mechanisms that are compartmentalized within dendritic subregions of pyramidal neurons. This heterogeneity likely permits the selective modulation of specific circuits contributing to different aspects of cognitive function.

Title: Effects of nano-molar Abeta 1-40 on excitatory synaptic transmission

Authors: *R. M. LAZARENKO, L. L. ROUHANA, B. EDBERG, X. GAO, Q. ZHANG
Dept Pharmacol, Vanderbilt Univ., Nashville, TN

Abstract: Alzheimer's is a chronic disease of elderly and aggregated amyloid beta (Aβ) is the major component of plaques found in patients' brains. Aβ is known to disrupt synaptic transmission and likely contributes to neurodegeneration. Among various isoforms of Aβ, Aβ(1-40) is the most abundant and less aggregative. Production of Aβ correlates with synaptic activity and can reach tens of nano-molar in vivo. Though, there is a documented role of Aβ on postsynaptic site, little is known about effect of Aβ on presynaptic terminals. Combining live cell imaging and patch clamp electrophysiology, we examined how elevated Aβ(1-40) levels impact presynaptic function.
We found that acute application of 100 nano-molar Aβ(1-40) leads to cell membrane instability, swelling and fragmentation of neurites, which is unlikely caused by insoluble Aβ(1-40) aggregates as dynamic light scattering measurement shows no proteinous particles larger than 100 nm. At 10 nM, Aβ leads to increase of mEPSC amplitude and decrease of frequency without measurable changes in cell morphology. At 1 nM - effects are similar to 10 nM but milder.
The reduced frequency of minis may reflect the lower vesicle release probability (Pv), availability of fewer synapses, impaired vesicle recycling, etc. By comparing normalized evoked responses to 30 Hz/20 pulses trains of local electric stimulation of presynaptic inputs, we found decreased Pv in the presence of Aβ(1-40). NMDA/AMPA ratio in the presence of 10 nM beta amyloid was slightly increased, likely corresponding to the increase of mEPSC amplitude. Using single Qdot imaging, we have identified that the decrease of Pv is due to the lack of fast vesicle recycling not the decrease of readily releasable pool. Using simultaneous FM, we have confirmed that fast release and retrieval of synaptic vesicles are impaired. Slow vesicle recycling is unaltered. By labeling three representative synaptic vesicle proteins, synaptobrevin II,

synaptophysin and vesicular glutamate transporter 1, with pH-sensitive GFP variant (a.k.a. pHluorin), we have identified that the proportional retrieval of vesicular proteins remain the same despite significantly slower vesicle recycling. In addition, we did not detect any significant elevation of baseline intracellular Ca2+ concentration or Ca2+ channel conductance. Therefore, we concluded that the likely cause of presynaptic impairment is the interaction between soluble Aβ(1-40) and presynaptic membrane. Although moderate, this effect may be countable for neurite degradation or neuronal death as prolonged or dramatic surge of Aβ(1-40) in vivo can break down membrane homeostasis, especially at axonal terminals.

Title: Leptin depresses excitatory synaptic transmission onto dopamine neurons of the ventral tegmental area

Authors: *J. L. THOMPSON[1], S. L. BORGLAND[2]
[1]Anesthesiology, Pharmacol. and Therapeut., [2]Anesthesiology, Pharmacol. & Therapeut., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Leptin is an adipocyte-derived cytokine that can act in the brain to suppress feeding and maintain energy homeostasis. Leptin regulates food intake via activation of leptin receptors in the hypothalamus. Additionally, leptin activates its receptors in the ventral tegmental area (VTA), a critical site for neuroadaptations to rewarding stimuli, and decreases responding for food, heroin, and intracranial self-stimulation. While leptin can decrease intrinsic excitability of dopamine neurons in the VTA, it is unknown if leptin can modulate excitatory synaptic transmission in this brain region. Because plasticity of glutamatergic synapses onto VTA neurons can encode predictive information about reward, we tested how leptin modulates excitatory synaptic transmission onto dopamine neurons. Using whole-cell patch clamp electrophysiology in mouse midbrain slices, we tested the effects of leptin on firing and evoked

α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) or N-methyl-D-aspartate receptor (NMDAR)-mediated excitatory post synaptic currents (EPSCs) onto VTA dopamine neurons. Consistent with previous reports, we found leptin (100 nM) modestly depressed firing rate. Interestingly, leptin (15 min, 100 nM) caused a long-lasting reduction of NMDAR EPSCs reaching a maximum of 26 ± 2.9 % . Similarly, leptin (15 min, 100 nM) inhibited AMPAR EPSCs to a maximum of 20 ± 3.1%. Taken together, these results indicate that while leptin modestly and transiently inhibits firing, it causes a long-lasting suppression of glutamatergic synaptic transmission onto VTA dopamine neurons. Leptin-induced weakening of synaptic strength may underlie the inhibitory effects of leptin on appetitive behavior for rewarding stimuli.

Title: CCK triggers plasticity of GABA synapses in the dorsomedial hypothalamus through astrocytic ATP release

Authors: *K. M. CROSBY, J. S. BAINS, Q. J. PITTMAN
Univ. Calgary, Calgary, AB, Canada

Abstract: The dorsomedial hypothalamus (DMH) plays a key role in integrating and relaying satiety signals within neural networks that regulate energy intake and expenditure. We have previously demonstrated that GABA synapses in the DMH are plastic, such that food deprivation-induced activation of the stress response shifts the polarity of inhibitory plasticity from endocannabinoid-mediated LTD to nitric oxide-mediated LTP. Cholecystokinin (CCK), a satiety peptide and neuromodulator, suppresses food intake via actions in the DMH. Thus, we asked how CCK would impact the plasticity of DMH GABA synapses. We conducted experiments on horizontal hypothalamic slices containing the DMH from male Sprague-Dawley rats (postnatal day 21-30). Whole cell recordings were obtained from DMH neurons and an extracellular stimulating electrode was positioned inside the DMH to activate synaptic inputs to

these neurons. Consistent with previous findings, high frequency stimulation elicited a robust, long-term depression of GABA synapses. Interestingly, in the presence of CCK, the same stimulus resulted in a long term potentiation at these synapses.
This plasticity is mediated by CCK_B receptors that are localized on nearby astrocytes. Activation of these receptors triggers a functional up-regulation of the group I metabotropic glutamate receptor 5 (mGluR5), also localized on astrocytes. This results in release of the gliotransmitter, ATP, which subsequently acts on purinergic receptors at the presynaptic terminal to trigger an increase in GABA release. Overall, our results provide new insights into synaptic mechanisms that may contribute to the central
satiety actions of CCK in the DMH.

Title: Hypothalamic projections from suprachiasmatic nucleus according to vasoactive intestinal peptide and vasopressin immunoreactivity in the Cebus apella monkey.

Authors: *L. M. CAMPOS[1], L. PINATO[2], M. I. NOGUEIRA[1,2]
[1]Anat., Inst. of Biomed. Sci., Saõ Paulo, Brazil; [2]Speech-Language and Hearing Therapy, São Paulo State Univ., Marília, Brazil

Abstract: The suprachiasmatic nucleus (SCN) of the hypothalamus, considered the endogenous master clock, in the most of studied species, contains a variety of different neurons that tend to form two major subpopulations within the nucleus, one that produces vasoactive intestinal peptide (VIP) and other vasopressin (VP). The immunoreactive (IR) fibers derived from the VIP and VP IR cells of the SCN present morphological characteristics that allow their specific tracking in long distances within the hypothalamus. In the present investigation we aimed first map VIP and VP IR terminals in hypothalamic areas of the primate *Cebus apella* using immunohistochemistry for the neuropeptide VIP and VP. Our second aim was the identification of hypothalamic recipient areas from SCN using the mapping distribution of fibers IR associated

with morphological analysis of these two neuroactive substances. The VIP and VP IR fibers from SCN showed a specific morphology compared to other sources. The fibers are thinner and varicose with bulbs and buttons dilated irregularly spaced along their trajectories. VIP and VP IR fibers with characteristics from SCN were identified in the rostral anterior hypothalamic area and medial preoptic area, laterally to the lateral hypothalamic area, and more caudally in SPZV and retrochiasmatic tuberal area. In the morphological analysis of the intrinsic neurons to SCN, we found VP IR neurons grouped in two neuronal subpopulations with different measures (area, perimeter) in the shell portion of the nucleus. There was a higher density of VP IR fibers located in areas at the same level of SCN in coronal sections. These fibers proceeding toward the posterior hypothalamus and the medial periventricular areas compared with the VIP IR fibers. We also verified the coexistence of VIP and VP IR fibers in the hypothalamic areas analyzed. The results indicate that in the primate *Cebus apella* there is a similarity in the pattern of distribution of VIP and VP fibers in the hypothalamic areas and also in areas recipients from SCN projections when compared with nocturnal rodent species described in the literature.

Title: Investigating the neuromodulatory role of VAV-1, a Rho family guanine nucleotide exchange factor, in Caenorhabditis elegans

Authors: A. FRY[1], J. LABOY[1], *K. NORMAN[2]
[1]Ctr. for Cell Biol. and Cancer Res., [2]Albany Med. Col., Albany, NY

Abstract: *C. elegans* VAV-1, a conserved guanine nucleotide exchange factor that activates Rho/Rac GTPases, is the sole worm homolog of mammalian Vav proto-oncogenes. VAV-1 regulates a variety of rhythmic activities in *C. elegans*, and we suspected a role in the rhythm of locomotion since *vav-1* null worms are hyperactive. By utilizing neuronal GFP constructs, we found that *vav-1* mutants do not have any gross developmental defects. Using genetic and pharmacological techniques, we have determined that VAV-1 acts specifically in the nervous

system to regulate neuronal excitation and locomotory speed. To learn what neurons express *vav-1*, we generated transgenic strains expressing fluorescent *vav-1* reporters, and have found that a limited number of neurons, comprising multiple subtypes, including an interneuron and both GABA- and cholinergic motor neurons, express these reporters. We then generated transgenic strains in which VAV-1 is re-expressed specifically in the different neuronal subtypes identified. By expressing VAV-1 only in cholinergic neurons, we found that the hyperactive locomotion of *vav-1* null worms can be rescued to wild type levels. Additionally, *vav-1* null worms display a more robust full body contraction than wild type animals upon activation of the cholinergic neurons using channel rhodopsin, suggesting that the cholinergic neurons are hyperexcitable in the *vav-1* null background. Our data suggest that VAV-1 affects the nervous system through dense core vesicles (DCVs), which carry neuromodulatory molecules such as insulins, neuropeptides, and biogenic amine neurotransmitters. We found that VAV-1 is upstream of UNC-31/CAPS (Calcium-activated protein required for secretion), a known regulator of DCV release. Moreover, we have determined that EGL-3/PC2 (Proprotein convertase 2), required for neuropeptide processing, is not downstream of VAV-1. These results together suggest that VAV-1 exerts its effect on the nervous system by regulating a molecule(s) secreted by DCVs that is not a neuropeptide. We have preliminary evidence that VAV-1 negatively regulates insulin-like signaling-mediated processes, and thus are currently investigating whether *vav-1* null worms have altered insulin release from the nervous system. Specifically, we are investigating whether deregulated insulin release from cholinergic neurons is responsible for the *vav-1* null worm hyperactivity and pharmacological response. Our studies provide novel evidence for Vav proteins in regulation of dense core vesicle-released molecules, and may reveal an interesting role for insulins in modulating neural activity.

Title: Modulation of neuromuscular excitability by *C. elegans* neuropeptides

Authors: *D. TOUROUTINE[1], R. BHATTACHARYA[2], M. FRANCIS[2]
[2]Neurobio., [1]Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Neuronal excitability can be shaped by the actions of a host of neuromodulators including neuropeptides. Neuropeptides are known to play important roles in intercellular signaling across a wide range of organisms and cellular contexts. However, the mechanisms by which neuropeptides regulate cellular excitability remain poorly understood. We have begun to explore mechanisms underlying neuropeptide signaling using the model organism *C. elegans*, in which powerful genetic tools can be paired with electrophysiological and behavioral analysis. To identify potential neuromodulators, we generated a mutant form of the levamisole receptor (L-AChR), an ionotropic acetylcholine receptor (iAChR) responsible for excitatory signaling at the neuromuscular junction, that carries a gain-of-function leucine to serine mutation. Specific expression of the L-AChR(*gf*) transgene in muscles caused prolonged postsynaptic current responses. Importantly, L-AChR(*gf*) animals also exhibit easily identifiable locomotory phenotypes, including decreased speed and exaggerated muscle flexures during movement. We found that these behavioral effects required the activity of genes involved in dense vesicle biogenesis and secretion. To test whether neuropeptides may be required for the behavioral effects of L-AChR(*gf*) expression, we reduced the levels of specific pro-neuropeptide family members using RNAi. We found that five neuropeptide-like genes, including the cholecystokinin-like peptide NLP-12, are required to achieve the effects of chronic muscle hyperactivation in our model. The kinetics and amplitude of photo-evoked postsynaptic currents were not changed by loss of NLP-12, suggesting that this neuropeptide does not act directly on iAChRs to alter their function or localization. We are currently conducting additional electrophysiological experiments to elucidate mechanisms of action for NLP-12 and the other peptides identified from our screen, and the results of these experiments will be presented. Our results to date indicate that a network of neuropeptide signals act to modulate neuromuscular excitability and locomotion. By characterizing the neuropeptides and signaling pathways involved in motor control, we hope to elucidate conserved mechanisms for neuropeptide regulation of cellular excitability that will be relevant for organisms ranging from nematodes to humans.

Title: Prenatal lipopolysaccharide-induced immune activation alters nociception in the adult rat

Authors: *S. A. RANA, A. C. KENTNER, Q. J. PITTMAN
Hotchkiss Brain Institute, Physiol. and Pharmacol., Univ. of Calgary, Calgary, AB, Canada

Abstract: Peripheral inflammation experienced during early development can have profound effects on subsequent pain sensitivity. Lipopolysaccharide (LPS)-induced immune activation during the prenatal and neonatal periods of life produces long-term changes in febrile responses to a similar immunogen exposure in adulthood. Adult LPS exposure, which induces sickness behaviors, also produces hyperalgesia. In fact, previous research from our lab has shown that rats exposed to LPS on postnatal day 14 displayed enhanced baseline responses to nociceptive stimuli and elevated spinal cord cyclooxygenase-2 (COX-2); they also failed to mount the expected hyperalgesic response following adult LPS exposure and showed a reduction in spinal cord COX-2 expression compared with neonatally saline-treated rats. To determine whether prenatal immune activation will have similar effects on adult pain sensation, adult male Sprague-Dawley rats, born to dams exposed to 100 µg/kg LPS, 50 µg/kg LPS, or saline on gestational day (GD) 12, were examined for nociceptive responses to thermal and mechanical stimuli using the Hargreaves' Method (plantar test) and von Frey filament test, respectively; as well as, tumor necrosis factor (TNF) -α and COX-2 mRNA expression in the hypothalamus, and TNF-α, COX-2 and cannabinoid receptor type 1 (CB1) mRNA expression in the dorsal horn of the spinal cord, following adult LPS challenge. Preliminary results suggest, unlike neonatally-treated rats, GD 12 LPS-treated offspring do not exhibit altered baseline nociceptive (behavioral) responses and spinal COX-2 levels. Further, basal hypothalamic TNF-α and COX-2 transcript levels were elevated in the GD12 LPS-treated rats; and spinal TNF-α and COX-2 levels were elevated in GD12 LPS-treated rats only following adult LPS challenge compared to GD12 saline-treated rats. Spinal CB1 levels remained unaffected by both prenatal- and adult- LPS exposure. The present findings suggest that not only is adult pain sensation differentially affected by timing of early immune system activation, but also patterns of TNF-α and COX-2 mRNA expression differ across brain regions.

Title: The effect of prenatal maternal inflammation on the cerebellum of mouse offspring

Authors: *T. AAVANI[1], R. HAWKES[2], Q. J. PITTMAN[1]
[1]Physiol. and Pharmacol., Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada;
[2]Cell Biol. and Anat., Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Autism Spectrum Disorders (ASDs) are characterized by abnormal development in social, language, and sensorimotor behaviours. Systemic infection during pregnancy is known to be a possible non-genetic factor for the development of ASDs in offspring. Individuals with ASD have been shown to have not only cognitive deficits, but also deficits and delays in movement in which cerebellar function might play an important role. In previous studies, prenatal exposure to a viral-like agent has indicated Purkinje Cell (PC) loss in the cerebellum of offspring. The present study was designed to examine the effect of maternal inflammation on the organization of PCs as well as the behaviour of the offspring. Pregnant C57Bl/6 mice were injected with the viral mimetic poly(I:C) (20 mg/kg) or saline on gestational days 13, 14 and 15. Male and female pups from the prenatally-treated dams were sacrificed on postnatal day 18 for wholemount immunohistochemistry which was carried out using a monoclonal antibody raised against zebrin II (ZII). In another group of pups, rotarod and social interaction tests were tested on day 30. Our findings revealed that the pattern of PC stripes in the cerebellum changed subtly as a result of the prenatal immune challenge. Independent of sex, offspring of poly(I:C)-exposed dams showed an increase in the distance between the ZII immunopositive PC stripes in the anterior vermis relative to controls. In addition, the lateral extent of the cerebellum as well as the width of the ZII negative stripes were greater in the offspring of poly(I:C)-exposed mice. Also, the number of PCs revealed by the pan-PC marker calbindin and the circumference of lobules III and VII were also increased in the poly(I:C) group. Furthermore, these animals had motor deficits as revealed by the rotarod test. However, there was no significant difference in the social interaction test between the offspring of the poly(I:C)-treated dams compared to the control group. These preliminary findings therefore suggest that cerebellar development is abnormal in the offspring of dams that have been exposed to prenatal immune challenge.

Title: The effects of early life peripheral immune challenge on amygdala synaptic functioning

Authors: *A. SZUBRA
Neurosci., Univ. of Calgary, Calgary, AB, Canada

Abstract: Compelling evidence now suggests that early life immune challenges during key developmental stages can have long lasting effects on brain excitability, neurochemistry, and behaviour. Experimentally, perinatal and neonatal rat exposure to the inflammatory molecule lipopolysaccharide (LPS) has been shown to result in long term alterations in memory formation and fear response. Of particular interest in the study of amygdala functioning is the latter. There exists a growing body of work examining the way in which the amygdala shapes its circuitry in conjunction with fear association formation. As there may be synaptic changes in the amygdala as a consequence of neonatal inflammatory insults, the present research sought to examine the effect of early life peripheral inflammation on amygdala synaptic functioning in order to provide a mechanistic explanation for the ostensible behavioural changes previously described. Young C57Bl/6 rats were injected with LPS (100 µg/kg) or saline on post natal day 14, and sacrificed at 1 month of age. Whole cell voltage and current clamp recordings were taken in basolateral amygdala neurons while stimulating afferent pathways to these cells. Cell responses between neonatal LPS- and saline-pretreated animals were compared. Our findings revealed that cells in LPS-treated rats are more excitable with alerted glutamatergic inputs and more easily depolarized cell membranes when compared with saline treated controls. These findings provide a basis for future work, which will examine the mechanistic basis for these changes.

Title: *In vivo* transport of type A2 botulinum toxin

Authors: *M.-C. SHIN, N. AKAIKE
Kumamoto Hlth. Sci. Univ., Kumamoto City, Kumamoto Pref., Japan

Abstract: Type A botulinum toxin blocks not only ACh release from motor nerve terminals but also central synaptic transmissions such as glutamate, noradrenaline, dopamine, ATP, GABA, and glycine. In addition, the antero- and retrograde axonal transports of the neurotoxins via either motor or sensory neurons from peripheral tissues to CNS were reported. Futhermore, type A2 neurotoxin, A2NTX, injected into the rat left foreleg muscles was transported to the contralateral ones, suggesting the neurotoxin was transported retrogradely to spinal neurons through motor neuron of toxin-injected (ipsilateral) muscles side, and then transcytosed to contralateral motor neurons within spinal cord, after that the toxin was transported anterogradly via motor nerve from the contralateral spinal neurons to the unilateral soleus muscles as a possible explanation. Present study clearly showed that the toxin injection to rat left soleus muscles induced bilateral muscle relaxization in a dose-dependent fashion, although the contralateral muscle relaxization appeared after the complete inhibition of toxin-injected ipsilateral muscles. The muscle relaxation was faster and stronger in A2NTX than in A1LL. A1LL (BOTOX) was transported via both pathways of nerve and blood circulation to the contralateral muscle, but the contribution of axonal transportation was greater than blood. On the other hand, A2NTX was mainly transported to contralateral muscles via blood. In addition A1LL was more easily transcytosed to contralateral spinal neurons than A2NTX. It is also demonsterated that neurotoxins A1LL and A2NTX were carried from peripheral to CNS and vice versa by not only both antero- and retrograde axonal transports through either motor or sensory neurons but also blood circulation. 1

Title: Intrathecal administration of botulinum toxin A: Antiallodynic action and inhibition of excitatory synaptic transmission in the spinal dorsal horn

Authors: K. NEMOTO[1], *S. YAMAGUCHI[1], R. MATSUZAWA[1], T. TAKASUSUKI[1], T. TERASHIMA[1], T. FUKUSHIMA[2], T. OTSUBO[2], Y. HORI[2]
[2]Dept. of Physiol. and Biol. Information, [1]Dokkyo Med. University, Sch. of Med., Mibu, Japan

Abstract: Botulinum toxin type A (BoNT1A) is known to bind the presynaptic nerve terminal where BoNT1A is internalized into the nerve terminal, cleave synaptosomal-associated protein 25 (SNAP-25), which is a component of the SNARE complex. Thus, BoNT1A interferes with vesicle docking thereby inhibiting transmitter release from the presynaptic nerve terminal. It has recently been shown that intrathecal (IT) administration of BoNT1A attenuates inflammatory and neuropathic pain. In the present experiments, we have investigated the effects of IT BoNT1A on neuropathic pain induced by partial ligation of the sciatic nerve in adult ICR mice, with the final aim of clarifying the synaptic mechanisms of BoNT1A's antinociceptive actions. The sciatic nerve was partially ligated under halothane anesthesia. IT injection of BoNT1A was made according to the method described by Hylden and Wilcox (1980). Tactile allodynia was assessed by counting the frequency of withdrawal responses to the stimulation by von Frey filaments. IT injection of BoNT1A prior to nerve ligation did not exhibit apparent antiallodynic efficacy: in contrast, IT injection of BoNT1A one day after nerve ligation significantly attenuated allodynia and this attenuation was maintained for about ten days. In some experiments, the spinal cord was removed under ketamine-xylazine anesthesia and spinal slices were prepared. Tight-seal whole-cell recordings were made from neurons located in the superficial dorsal horn. In the presence of tetrodotoxin, bicuculline, and strychnine,spontaneously occurring miniature excitatory postsynaptic currents (mEPSCs) were recorded. The frequency of mEPSCs was found to be significantly lower in nerve-ligated BoNT1A-injected mice than in nerve- ligated saline-injected mice. The amplitudes of mEPSCs were not significantly different between these two groups. BoNT1A is known to cleave the SNAP-25 protein that is essential for transmitter release. Our preliminary Western blot analysis of spinal dorsal horn protein exhibited that the expression level of SNAP-25 was only slightly lower in nerve-ligated BoNT1A-injected mice than in nerve-ligated saline-injected mice. Taken all together, the present results seem to indicate that at least some part of antinociceptive effects of BoNT1A is produced by presynaptic inhibition of excitatory synaptic transmission in the spinal dorsal horn and that mechanisms other than cleavage of SNAP-25 are also involved in antinociceptive effects of intrathecally administered BoNT1A.

Title: The effects of HPC1/Syntaxin 1A gene knockout on the general anesthetic actions of sevoflurane

Authors: S. KOKUBU[1], R. MATSUZAWA[1], K. NEMOTO[1], T. FUKUSHIMA[1], S. YAMAGUCHI[1], *M. MAEKAWA[1], T. FUJIWARA[2], K. AKAGAWA[2], Y. HORI[1]
[1]Dept Physiol Biol Information, Dokkyo Med. Univ. Sch. Med., Tochigi, Japan; [2]Dept of Cell Physiol, Kyorin Univ. Sch. of Med., Tokyo, Japan

Abstract: We reported at the 2010 Society for Neuroscience meeting that the minimum alveolar concentration (MAC) of the volatile anesthetic sevoflurane in HPC-1/Syntaxin 1A-knockout (KO) mice was significantly greater than that in wild-type (WT) mice, although the precise mechanisms for this difference was unclear. Additionally, it is well known that HPC-1/Syntaxin 1A is a membrane protein that plays an integral role in the exocytotic release of neurotransmitter. Based on these, we hypothesize that the activity of HPC-1/Syntaxin 1A affects the potency of general anesthetics and that general anesthetics produce the anesthetic state via interaction with exocytotic machinery in the presynaptic terminals. To evaluate these hypotheses, we investigated the effects of sevoflurane on excitatory synaptic transmission in the spinal superficial dorsal horn.
We used adult (6- to 8-week-old) male KO mice and WT mice. Under anesthesia by ketamine and xylazine, the lumbar spinal cord was removed, and cross-sectional slices were prepared. Tight-seal whole-cell recordings were made from neurons located in the superficial dorsal horn. Excitatory postsynaptic currents (EPSCs) were evoked by electrical stimulation of the dorsolateral funiculus. The recordings were made at the holding potential of -70 mV in the presence of strychnine (1 mM) and bicuculline (10 mM). The perfusates were bubbled with sevoflurane through the use of a calibrated vaporizer. In order to measure the aqueous phase concentration of sevoflurane during experiments, 2 ml of the perfusates were sampled from the recording chamber. Chloroform was added as the solvent for liquid-liquid extraction, and gas chromatographic measurements of sevoflurane were performed.
Sevoflurane at the concentration of 0.5 mM reduced the amplitude of EPSCs to the same extent in both WT and KO mice (40-50% of the control). Sevoflurane at the concentration of 0.75 mM and 1.0 mM reduced eEPSC amplitude to 20-30% and 15-25% of the control, respectively, in WT mice. In contrast, the inhibitory effects of 0.75 mM and 1.0 mM sevoflurane were significantly weakened in KO mice (45-50% and 25-35% of the control, respectively). The

paired-pulse ratio of eEPSCs was consistently increased during the inhibition of the amplitude of eEPSCs.
These results suggest that sevoflurane produces the anesthetic state, at least in part, via interaction with exocytotic machinery in the presynaptic terminals and that the activity of HPC-1/Syntaxin 1A affects the actions of general anesthetics on excitatory synaptic transmission in the spinal dorsal horn and thereby affects the potency of general anesthetics.

Title: Effect of green odours on stress induced up regulation of sympathetic neurotransmission.

Authors: *J. M. SODEN, N. A. LAVIDIS
Sch. of Biomed. Sci., The Univ. of Queensland, St Lucia, Australia

Abstract: Chronic stress results in the up regulation of neurotransmission from sympathetic varicosities. Previously, we reported that specific plant derived odours such as *cis*-3-hexen-1-ol (hexenol), *trans*-2-hexenal (hexenal) and α-pinene are effective at reducing the stress induced increases in sympathetic neurotransmission. In the present study, we examined the effectiveness of the combinations of these plant derived odours in reducing the stress induced increases in sympathetic neurotransmission. Six week old Balb/c mice were exposed for 11 days to minimal stress or concurrent (predator plus social deprivation) stress with and without either vehicle (tri-ethyl citrate), green odour (hexenol (0.03%) with hexenal (0.03%) in tri-ethyl citrate), or Praescent™ (hexenol (0.03%), hexenal (0.03%) and α-pinene (0.015%) in tri-ethyl citrate). The odours were delivered by spraying 0.2 mLs on the bedding material, 3 times per day. N = 16 for each treatment. Following treatment, animals were sacrificed by cervical fracture and both vasa deferentia were dissected. The prostatic end of the vas deferens was stimulated. Sympathetic varicosities were visualised using DiOC2(5)-fluorescence. Excitatory junction currents (EJCs) were recorded using focal extracellular recordings with 10 to 15 µm tip diameter electrodes. The mean EJC amplitude (mEJC) and success rate of recording EJCs was determined. The mEJC for:

minimal stress was 37±16μV; concurrent stress was 118±27μV; concurrent stress with Praescent™ was 16±5μV; and concurrent stress with green odour was 28±9μV. There was a significant increase ($P<0.01$) in mEJC between minimal and concurrent stress of 311±41%. Both Praescent™ and green odour significantly reduced the stress induced increases in mEJC shown in the concurrent stressed vas deferens, ($P<0.01$). Our findings indicate Praescent™ and green odour are effective in reducing the chronic stress induced increases in sympathetic neurotransmission.

Title: Effects of A2a adenosine receptor knockdown on neuronal nitric oxide synthase (nNOS) enzyme expression levels in primary cell culture from dorsal medulla oblongata of neonate spontaneously hypertensive and normotensive rats.

Authors: *M. A. COSTA[1], J. P. MATSUMOTO[1], D. C. CARRETTIERO[2], D. R. FIOR-CHADI[1]
[1]Biosci. Institute/University of São Paulo, São Paulo, Brazil; [2]Univ. of ABC, Brazil, Brazil

Abstract: Introduction: Adenosine and nitric oxide (NO) acts as modulator of sympathetic activity, with modulatory action on cardiovascular control. The relationship between NO and adenosine in the peripheral system is well established, but this relation in the nucleus tract solitary (NTS) is still being studied. The purpose of the present study was to analyze the effect of A2a knockdown on the nNOS mRNA in cultured cells from the dorsomedial medulla oblongata of normotensive (WKY) and spontaneously hypertensive (SHR) rats.
Methods: All the procedures were performed in accordance with the Institutional Guidelines for Animal Experimentation (CEA/IB-USP). Cell cultures were made using the dorsomedial

medulla oblongata region of one-day old WKY and SHR (n=15). Cells cultures were infected by GIPZ lentiviral vector containing shRNAmir to A2aR and non-silencing GIPZ lentiviral shRNAmir as control. After three days in culture, cells of the medulla oblongata of WKY and SHR were exposed at approximately $1x10^8$ TU/ml for five hours. Three days after the infections, the RNA was extracted for real time PCR analysis of both A2aR and nNOS mRNA levels. Results were analyzed by unpaired Students t test and a p-value<0.05 was considered to indicate statistically significant differences.

Results: Results are expressed as fold-change ± SEM. Although it is difficult to infect primary neuronal culture, this study demonstrated a percentage up to thirty per cent of infected cells in both strains. This infection level by ADORA2a shRNA produced a significant knockdown of A2aR mRNA in both strain (WKY: 0.75±0.03 and SHR: 0.60±0.09, p<0.05), followed by a concomitant reduction in the levels of the nNOS enzyme when compared to non-silence control (WKY: 0.77±0.03 and SHR: 0.69±0.04, p<0.05).

Conclusion: We suggest that in primary neuronal culture from dorsal medulla oblongata of neonate spontaneously hypertensive and normotensive rats, the effects of A2aR might be mediated by NO, at least in part. These results reinforce the existence of a cross-talk between A2aR and NO in the central control of cardiovascular function.

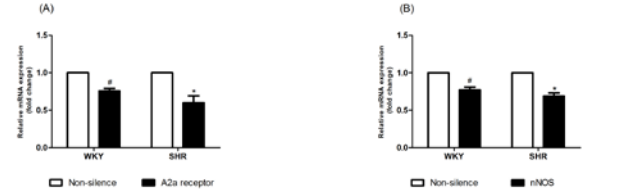

Fig.1. Quantitative analysis adenosine A2a receptor (A) and nNOS (B) mRNA expression evaluated in primary culture cells of the dorsomedial medulla oblongata of SHR and WKY rats after knockdown of A2a adenosine receptor. Both A2a adenosine receptor and nNOS mRNA expression were decrease when compared to respective control. Values are shown as mean ± SEM (n = 3 for mRNA experiments). # p<0.05 compared with WKY non-silence control and * p<0.05 compared with SHR non-silence control. Student's t test was employed in the statistical analysis.

Title: Effects on NMDA receptor activity by positive allosteric modulation of mGluR5 receptors in dysbindin-1 null mutant mice.

Authors: *J. I. PEÑA BRAVO[1], J. M. ROOK[2], P. J. CONN[2], A. LAVIN[1]
[1]Neurosci., Med. Univ. of South Carolina, Charleston, SC; [2]Pharmacol., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Understanding the mechanism behind N-methyl-D-aspartate (NMDA) receptor hypofunction in prefrontal cortex pyramidal neurons (PFC) is important for the development of novel treatments for schizophrenia and related psychiatric disorders. The activity of cortical pyramidal neurons is regulated by fast-spiking (FS) GABA interneurons. Most recent advances at modulating NMDA receptor activity are the use of allosteric modulators of mGluRs. In our study we are specifically interested in testing the putative enhancing effects of VU0360172, a mGluR 5 positive allosteric modulator (PAM), on NMDA receptor activity. In previous studies done in our lab we have used a mouse carrying a null mutation in the dtnbp I gene as a model for schizophrenia. This gene encodes for dysbindin, a protein involved in vesicular trafficking and exocytosis and expressed in glutamate producing neurons of the PFC.
In order to examine excitatory neurotransmission, we performed whole-cell patch clamp recordings of excitatory post synaptic currents (EPSCs) in brain slices from male wild type (WT), heterozygous (HET) and mutant (MUT) mice (35-60 days of age). We evaluated the contribution of NMDA receptors to the amplitude of evoked excitatory postsynaptic currents (eEPSCs) and amplitude and frequency of spontaneous excitatory postsynaptic currents (sEPSCs) and compared between genotypes. To control for any GABA receptor contribution we added picrotoxin (50 μM), a selective GABA blocker, to a group of recordings. In our preliminary results, we found a trend toward an increase of NMDA-mediated eEPSCs in HET mice following VU0360172 administration; this was not detected in WT or MUT. We detected a significant main effect on NMDA-mediated eEPSC amplitude between the genotypes. Interestingly, when only AMPA currents were blocked, but GABA and NMDA currents were intact, we found that VU0360172 significantly decreased eEPSCs amplitude in MUT mice, suggesting that the drug might be acting on mGluR5 receptors coupled to NMDAR located in GABA neurons.
Our results suggest that the mGluR5 PAM increases NMDA currents in cases in which the population of NMDA receptors is still intact (HET), but also seems to modulate NMDA currents in GABAergic neurons. This mechanism supports results shown by Xi, D. et al (2009) who has demonstrated a differential distribution of NR2A-containing NMDA receptors, known to have distinct agonist sensitivity and deactivation rates, in GABA interneurons in the PFC.

Title: Comparative studies of nine tertiary oximes on reactivation of OP nerve agent-inhibited AChE in the CNS

Authors: *T.-M. SHIH, I. KOPLOVITZ, R. KAN, J. MCDONOUGH
US Army Med. Res. Inst. Chem Defn, Aber Prov Grd, MD

Abstract: Organophosphate nerve agents irreversibly inhibit the enzyme acetylcholinesterase (AChE), which leads to an excess of the cholinergic neurotransmitter acetylcholine in the synapses, causing numerous toxic effects, such as hypersecretions, tremors, convulsions, respiratory distress and death. The current nerve agent treatment regimen includes 2-pralidoxime (2-PAM) to reactivate inhibited AChE. The quaternary structure of this oxime, however, does not allow it to cross the blood brain barrier to reactivate brain AChE and to mitigate CNS toxicity. We have shown earlier that the tertiary oxime monoisonitrosoacetone (MINA) provided some AChE reactivation in the brain, enhanced survival and mitigated the seizure activity following nerve agent exposure. In this study, the *in vivo* reactivating capabilities of several new tertiary oximes, diacylmonoxime (DAM), N,N-diethyl-3-(2-(hydroxyimino) acetoxy) propan-1-aminium chloride (DHAP), RS194B, JK-3-38, SWRI48A, SWRI53A, Pro-2-PAM, and diethyxime, were compared to each other and to MINA, following subcutaneous nerve agent exposure. Guinea pigs were challenged with a 1.0 x LD_{50} dose of sarin (GB), cyclosarin (GF) or VX 15 min after administration of atropine methylnitrate (2.0 mg/kg, im), followed 15 min later by a test dose of the oxime. Four to eight doses (ranging from 5.6 to 240.0 mg/kg, im) of each oxime were tested. The animal was euthanized 45 min after oxime treatment; blood was collected and target tissues (brain regions, diaphragm, heart, skeletal muscle) were harvested. AChE activity was measured with the Ellman assay. Of these tertiary oximes, pro-2-PAM and JK-3-38 enhanced the toxicity of sarin at doses above 25 and 35.5 mg/kg, respectively. In peripheral tissues pro-2-PAM provided the greatest AChE reactivation (21-64%), while SWRI53A showed reactivation (15%) only at the highest dose (180 mg/kg), with the rank order of pro-2-PAM > RS194B = JK-3-38 > DHAP > MINA > diethyxime > DAM = SWRI48A = SWRI53A. In the CNS tissues, MINA displayed the highest capacity to reactivate AChE (2-31%), while DAM provided minimum reactivation (3%) even at the highest dose (129 mg/kg), with the rank order of MINA > pro-2-PAM > DHAP > SWRI48A = SWRI53A = RS194B = diethyxime > JK-3-38 = DAM. Thus, the findings suggest that like the quaternary oximes,

tertiary oximes show different reactivation capacities against AChE inhibited by specific nerve agent in the periphery or in the CNS. The protective efficacy of these tertiary oximes against nerve agent exposure is currently under investigation.

Title: The role of Pcp4 in synaptic transmission of the CA2 region of the hippocampus

Authors: *A. N. PETERSEN, N. Z. GERGES
Cell Biology, Neurobio. & Anat., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Purkinje cell protein 4 (Pcp4) is a calmodulin-binding protein highly expressed in the CA2 region of the hippocampus but absent from the CA1 and CA3. Calmodulin binding proteins are important for synaptic plasticity due to their ability to regulate the activation of Ca2+/CaM-dependent enzymes (e.g. calcineurin and CaMKII) which modulate α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) function and trafficking. Pcp4 is required for long-term depression (LTD) in Purkinje cells, as well as cerebellar-dependent learning. However, the role of Pcp4 in hippocampal synaptic plasticity and learning and memory is unknown. We have investigated the role of Pcp4 in CA2 synaptic transmission using a combination of molecular biology and electrophysiology. We find that AMPAR-mediated synaptic transmission is regulated by Pcp4 in a bidirectional manner, with acute overexpression causing a reduction in AMPAR responses while its knockdown enhances AMPAR responses. These results suggest a role for Pcp4 in the regulation of AMPAR in the hippocampus.

Title: Long-term plasticity in identified classes of somatostatin- and parvalbumin - expressing interneurons in the mouse hippocampus

Authors: *O. C. VASUTA[1], I. LAPLANTE[1], K. ELAYOUBI[1], J. HUANG[2], J.-C. LACAILLE[1]
[1]1GRSNC and Dept. of Physiology, Fac. of Med., Univ. of Montreal, Montreal, QC, Canada; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The hippocampus contains a heterogeneous population of interneurons (INs), which play key roles in modulating the physiology of the local circuits, enabling them to engage in coherent activities. The behavioral correlates of these activities in hippocampus are memory acquisition and space representation. The role of each type of IN may be specifically shaped through plasticity mechanisms at their synapses, and we have previously described a hebbian form of long-term potentiation (LTP) induced through mGluR1, at the synapses between CA1 pyramidal cells and oriens/alveus INs. We now examine more specifically which classes of INs express this plasticity taking advantage of two lines of mice, the somatostatin (SOM)-Cre and parvalbumin (PVALB)-Cre lines, crossed with Flox-EYFP reporter mice. In hippocampus, YFP-labeled SOM-INs are mostly detected in CA3 and CA1 oriens/alveus layers and in DG hilus, while YFP-labeled PVALB-INs are mostly present in or around the pyramidal and granular layers. Immunofluorescence analysis in CA1 area of SOM-Cre mice revealed that all YFP-labeled cells expressed SOM, while less than 5% of them were immunoreactive for PVALB. Similarly, in the PVALB-Cre mice, all YFP-labeled CA1 cells were immunoreactive for PVALB, but only 5% of them for SOM. By using electrophysiological recordings and minimal stimulation in YFP-expressing INs of acute hippocampal slice from these mice, we find that LTP is induced by theta-burst stimulation (TBS) paired with depolarization in CA1 SOM-INs, but not in PVALB-INs. Moreover, LTP did not occur when the induction protocol consisted of either TBS or depolarization alone. LTP induced by the paired protocol is mGluR1-dependent and was blocked by an mGluR1 but not an mGluR5 antagonist. A similar pairing protocol induces a depression of synaptic transmission in PARV-INs. These data indicate that theta burst stimulation induces hebbian LTP through the activation of mGluR1s specifically at the excitatory synapses of somatostatin-expressing interneurons in CA1 hippocampus, and provides the

background for further investigating the role of this cell type-specific plasticity in regulating the local neuronal circuit and hippocampal function.

Title: Chronic nicotine hinders hippocampus-dependent learning and memory in female rats

Authors: *R. BORGES-GARCIA[1], M. BEHAIRY[2], M. PEREZ-PINZON[3], H. BRAMLETT[4], A. P. RAVAL[2]
[1]Univ. of Miami, Miami, FL; [2]Univ. of Miami, Dept. of Neurol., Miami, FL; [3]Univ. of Miami, Dept. of Neurology,, Miami, FL; [4]Neurosci. Program, Univ. of Miami Dept. of Neurolog. Surgery, Miami, FL

Abstract: The rise in the number of female smokers is a major public health concern in the United States. Currently 22 million (22 %) American women smoke cigarettes and even though the detrimental effects of smoking-derived nicotine on health are well-established, giving up a smoking habit is more difficult for women than for men. Women metabolize nicotine faster than men and that influences smoking behavior, causing more dependence and increasing the associated risks. Most prior studies to understand the mechanisms of nicotine dependence were carried out on male experimental animals and were focused on identifying the effects of nicotine on its receptors; however, effects of nicotine unique to females warrant investigation. Recently, we demonstrated that chronic nicotine exposure attenuates short-term synaptic plasticity in the hippocampus of female rats. Hippocampus plays important roles in long-term memory and spatial navigation; therefore, we further investigated effects of chronic nicotine on hippocampus-dependent learning and memory. Twenty female rats were randomly assigned to either a nicotine

(4.5 mg/kg/day) or saline treatment. Starting on day 16 of nicotine/saline treatment, rats were tested for their hippocampus-dependent cognitive capabilities using the Morris water maze, using a 7-day testing paradigm. The first 4 days measured learning capabilities (learning the position of a platform), the 5th day measured memory (memory of platform location when platform is removed), and the 6th and 7th days measured working memory (learning a new platform location). The results are presented as Mean ± SEM of latency time in seconds. During four days of learning paradigm, nicotine exposed rats took longer time to find platform (40±3s, 37±4s, 39±3s and 41±2s) as compared to saline (36±4s, 31±4s, 31±5s and 26±2s). The results of this test demonstrated significant difference in latency period of nicotine and saline-treated female rats on the 4th day ($p < 0.001$). The outcome of the long-term memory testing performed on fifth day demonstrated that there was a distinct difference between the saline and the nicotine-exposed groups. Similarly, the working memory task demonstrated that saline-exposed rats performed better the nicotine-exposed rats. The nicotine-exposed rats took 38 and 36 seconds to find the platform on the first and second trial respectively, as compared to 36 and 29 seconds in saline group. Overall, the significant increase in latency period in the nicotine-exposed group suggested deficits in spatial learning and memory performance.

Abstract: Nogo-A is a well described inhibitor of axonal outgrowth in the CNS. However, the protein may have additional physiological functions which are not yet well characterized. Although the main expression of Nogo-A in the adult CNS is in oligodendroctyes, Nogo-A is also present in subpopulations of neurons and at synapses, e.g. in the hippocampus and the neocortex. In this study, we analyze the influence of the neurite outgrowth inhibitor Nogo-A on

synaptic transmission and long-term synaptic plasticity (long-term potentiation; LTP) by applying function blocking antibodies against Nogo-A or a blocking peptide of the Nogo receptor NgR1 (NEP 1-40) on acute cortical slices of the rat primary motor cortex. Both treatments enhanced LTP significantly. Subsequently, we trained antibody-treated animals in a motor learning task which requires skilled forelimb reaching. Anti-Nogo-A treated rats showed faster learning of the task and reached higher scores than the control antibody infused animals. These results show a new role of Nogo-A as a negative regulator of synaptic plasticity in the sensory-motor cortex and as an influential regulatory factor for motor learning *in-vivo*. The consequences of these findings for functional recovery and rehabilitation after CNS injury will be analysed in further steps.

Title: Long-term potentiation of temporoammonic-CA1 synapses in awake, freely moving rats

Authors: *J. GONZALEZ[1], I. S. MORALES[1], D. M. VILLARREAL[1], B. E. DERRICK[1,2]
[1]Biol., U Texas San Antonio, San Antonio, TX; [2]The Neurosci. Inst. of UTSA, San Antonio, TX

Abstract: Although hippocampal memory function traditionally has been viewed to occur through the relay of perforant path (PP) input to the dentate gyrus (DG) and the ensuing activation of the “tri-synaptic loop,” hippocampal area CA1 also receives direct cortical input via the temporoammonic (TA) path. Given the paucity of *in vivo* examinations of TA-CA1 synaptic plasticity, we utilized current source density analysis, paired pulse stimulation and high frequency stimulation (HFS) to characterize CA1 field responses in intact rats following stimulation of the medial aspect of the angular bundle, and investigated long-term potentiation (LTP) at medial TA (mTA)-CA1 synapses in freely moving rats. Our data demonstrate independent current sinks in the *stratum lacunosum moleculare* of areas CA1 and CA3 following stimulation of the angular bundle, indicating locally generated responses. Medial TA-CA1 field

excitatory postsynaptic potentials (fEPSP) exhibited paired pulse facilitation, contrasting the paired pulse depression observed with medial PP responses in the DG and CA3. Medial TA-CA1 fEPSPs displayed an onset of 1.5-3 ms and followed 100 Hz stimulation, indicating mTA-CA1 fEPSPs are monosynaptic. Medial TA-CA1 and contralateral CA3 (cCA3)-CA1 fEPSPs were collected for at least 5 days prior to mTA-CA1 LTP induction. LTP of mTA-CA1 fEPSPs was then induced by 400 Hz theta burst stimulation (TBS) of the medial aspect of the angular bundle in awake rats at current intensities that produce a half maximal CA1 fEPSP. A one hour post-TBS collection of mTA-CA1 and CA3-CA1 fEPSPs demonstrated a sustained LTP of mTA-CA1 fEPSPs (n=9) measuring 144 ± 11 percent of baseline. cCA3-CA1 fEPSPs (n=6) did not potentiate after mTA TBS, indicating mTA-CA1 LTP was input specific. Daily measurement of mTA-CA1 and cCA3-CA1 fEPSP slopes indicate mTA-CA1 LTP, on average, decays to baseline within 6 days after LTP induction, comparable to the 5-7 day LTP observed at PP-DG synapses. Together, these data suggest *in vivo* mTA-CA1 fEPSPs are locally generated, monosynaptic and exhibit long-lasting LTP in behaving rats. Given the proposed novelty detection function of TA-CA1 input, mTA-CA1 LTP may encode novel spatial stimuli and contribute to the proposed comparator (match-mismatch) function of CA1.

Title: Reelin, an extracellular matrix protein linked to early onset psychiatric diseases, drives postnatal development of the prefrontal cortex.

Authors: *J. IAFRATI, J. OREJARENA, O. LASSALLE, L. BOUAMRANE, P. CHAVIS
INMED INSERM U901, MARSEILLE, France

Abstract: Reelin is a large secreted glycoprotein present in the brain extracellular matrix. In the postnatal and adult hippocampus reelin signalling modulates synaptic plasticity and our group has previously shown that reelin controls the maturation of excitatory transmission and regulates the homeostasis of glutamatergic receptors.
Reelin dysfunction has been proposed to contribute to the etiology of psychiatric disorders: levels of reelin are decreased by approximately 50% in the PFC of schizophrenic patients. Moreover disruption of the maturation of the PFC functions participates to several psychiatric diseases such as schizophrenia. However the role of reelin in maturation and plasticity of glutamate connectivity in the prefrontal cortex (PFC) has never been investigated. To study the impact of decreased levels of reelin on the maturation of PFC glutamatergic functions, we took advantage of the Heterozygote Reeler Mice (HRM) which exhibits reduced reelin levels.
We combined ex-vivo electrophysiological recordings, 3D imaging and behavioural approaches to study synaptic plasticity in the PFC from wild-type and HRM from young to adult. We found that long term potentiation, a leading synaptic model for memory storage is abolished in HRM compared to wild-type. This is correlated with a lower dendritic spines density in HRM and to changes in glutamatergic receptors content. Treatment with glutamatergic antagonists restored spine density and synaptic plasticity. We propose that dysregulation of glutamatergic synapses due to a decrease in reelin content could lead to the dysfunction of the PFC.

Title: CPEB3 mediates the maintenance of LTP and the perpetuation of memory storage by regulating the translation of key synaptic components

Authors: *L. FIORITI[1], C. MYERS[1], Y. HUANG[1], X. LI[1], P. TRIFILIEFF[1], E. R. KANDEL[1,2,3]
[1]Columbia Univ., NEW YORK, NY; [2]Howard Hughes Med. Inst., New York, NY; [3]Kavli Inst. for Brain Sci., New York, NY

Abstract: Long-term memories are persistently maintained in the brain through long-lasting changes in the strength and number of synaptic connections. Although the cellular and molecular mechanisms underlying induction of memories have been extensively studied, those which mediate the maintenance of long-term memories and of the associated synaptic plasticity, are less well understood. In Aplysia and Drosophyla the persistence of synaptic plasticity and memory is mediated by the regulated activation of a self-sustaining translational regulator ApCPEB and Orb2 (Si et al, 2003, 2010). These findings raise the question whether such mechanism is also conserved in vertebrates, thus constituting a general system for the perpetuation of memory. To address this issue, we have identified the murine homolog of the memory-related invertebrate CPEB, called CPEB3 (Theis et al, 2003) and studied its role in the induction and maintenance of hippocampus-dependent forms of explicit long-term memory.
We generated a CPEB3 conditional knock-out mouse strain and found that genetic elimination of CPEB3 impairs the persistence of hippocampus-dependent spatial memory, as evidenced by both spatial recognition and Morris water maze tests. We then investigated the electrophysiological and molecular bases for the CPEB3-KO-related deficit in memory maintenance. We also found that the long-term maintenance - but not the induction - of learning-related long-term plasticity of hippocampal synapses is impaired in CPEB3-KO mice. At the molecular level, we found a significant reduction in the learning-induced synthesis of the glutamatergic AMPA receptor subunits GluA1 and GluA2, which have a critical role in hippocampus-dependent synaptic plasticity. Taken together, this behavioral, electrophysiological, and molecular evidence identifies CPEB3 as a key molecular mediator of the persistence of long-term forms of behavioral memory in the mammalian brain through translational regulation of key components of the synaptic machinery.

Title: NR2D-containing NMDA receptors regulate cerebellar synaptic plasticity and learning

Authors: *C. DUBOIS[1,3], L. SUN[2,3], P. M. LACHAMP[3], M. MISHINA[4], S. J. LIU[1,3]
[1]Dept. of Cell Biol. and Anat., [2]Neurosci. Ctr. of Excellence, LSUHSC, New Orleans, LA; [3]Dept. of Biol., PennState Univ., State College, PA; [4]Dept. of Mol. Neurobio. and Pharmacol. Grad. Sch. of Med., Univ. of Tokyo, tokyo, Japan

Abstract: Fear conditioning can induce a sustained enhancement in GABA release onto cerebellar Purkinje cells, highlighting the involvement of long term potentiation (LTP) of inhibitory transmission. We have shown that activation of NMDA type glutamate receptors (NMDARs) can induce a long-lasting increase in GABA release from stellate cells (I-LTP). Here we investigated the role of NR2D-containing NMDARs in the induction of presynaptic I-LTP and fear conditioning learning.
Burst stimulation of presynaptic parallel fibers (PF, 4 depolarizing pulses at 100 Hz) can activate extrasynaptic NMDARs and evoke NMDAR currents. Application of PPDA which preferentially blocks NR2C and NR2D-containing receptors reduced the synaptic current amplitude. The isolated currents had slower decay kinetics than PPDA-insensitive currents, suggesting the expression of functional NR2D-containing NMDARs in stellate cells.
Repetitive stimulation of PF with either 5 or 15 depolarizing trains (4 pulses at 100 Hz) triggered a lasting increase in mIPSC frequency, inducing an NMDAR-dependent form of presynaptic I-LTP. The presence of PPDA blocked the I-LTP, whereas ifenprodil, a selective NR2B blocker, did not prevent the potentiation. Similarly, a low concentration of CPP, that preferentially blocks NR2A and NR2B-containing NMDARs, also failed to prevent the development of I-LTP. Thus NR2D receptors appear to be required for the induction of presynaptic I-LTP.
We further examined the role of NR2D in I-LTP using NR2D knockout mice. As expected, deletion of NR2D markedly accelerated the decay time kinetics of NMDA currents. We found that 5 trains of depolarizations failed to induce a lasting increase in mIPSC frequency in NR2D knockout mice, indicating NMDARs that contain NR2D subunits are required for the induction of I-LTP. However I-LTP could be induced using a stronger stimulation protocol (15 trains of depolarizations).
We next investigated whether genetic deletion of the NR2D subunit alters cerebellar-dependent learning. NR2D KO mice required more US-CS pairings to exhibit fear conditioning learning than control animals. An open field paradigm indicated that this was due to altered learning rather than a change in locomotor function or in the anxiety state of the animal. Finally, NR2D KO mice exhibited normal motor learning in the rotarod paradigm.
In summary, we show here that functional NR2D-containing receptors are present in stellate cells. These receptors appear to be essential for the induction of I-LTP. These results might explain the elevated threshold for the induction of both I-LTP and fear learning in mice lacking functional NR2D receptors.

Title: Modulation of hippocampal long-term potentiation by a naturally occurring theta rhythm during REM Sleep

Authors: *M.-C. KUO, L. S. LEUNG
Dept. of Physiol. and Pharmacol., Univ. of Western Ontario, London, ON, Canada

Abstract: Hippocampal theta rhythm is prominent during behaviours such as walking and rapid eye movement sleep (REM), and plays a role in spatial navigation and learning. Previous studies have shown that the phase of the hippocampal theta rhythm modulates synaptic transmission and plasticity in anesthetized and behaving animals. Synaptic plasticity is a leading model of learning at the cellular level. It has been shown that in awake rats, high frequency electrical stimulation in hippocampal CA1 stratum (str.) radiatum delivered to the peak or trough of the local theta rhythm yields long-term potentiation (LTP) or long-term depression (LTD), respectively. Since REM may be important for learning, we hypothesized that the same may occur for the theta rhythm during REM theta. In addition, we studied the duration of LTP/LTD of tetanized and non-tetanized pathways. Field potentials in CA1 were recorded using a silicon probe with 16 channels at 50 μm intervals, and excitatory postsynaptic potentials (fEPSPs) at CA1 str. radiatum were recorded following stimulation of ipsi- or contralateral CA1 electrodes. After a stable baseline of recording, a stimulation burst consisting of 4 pulses at 400 Hz (~ 50% of maximum fEPSP amplitude) was delivered to one (tetanized) pathway at a particular phase of the REM theta rhythm; a total of 5 bursts were given. The slope of fEPSP was measured and current source density analysis was computed when available. Our results showed that bursts delivered during the positive phase of theta rhythm (at str. radiatum) induced LTP of 110-130% of the baseline fEPSP slope and bursts during the theta negative phase induced LTD of 80-90% of the baseline. The LTP and LTD lasted for 1-2 hr. When LTP developed in a tetanized pathway, a non-tetanized pathway showed LTP, LTD or no change; while LTD in the tetanized pathway appears to be accompanied by no change or LTD in the non-tetanized pathway. These data confirm that synaptic plasticity in the hippocampus can be modulated by naturally occurring REM theta. (Supported by a CIHR grant)

Title: Subregion specific PKA anchoring in the hippocampus is critical for synaptic tagging and contextual memory formation

Authors: *A. J. PARK[1], R. HAVEKES[1], T. NIE[1], T. HUANG[2], T. ABEL[1]
[1]Biol., [2]Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Synaptic plasticity is an input-specific neuronal process which requires highly coordinated molecular signaling achieved by subdomain-specific localization of signaling molecules. In the hippocampus, long-term potentiation (LTP) has been studied as a cellular model of memory storage. PKA has been reported as a key signaling molecule underlying LTP and memory formation. PKA-anchoring proteins (AKAPs) compartmentalize complex signaling by localizing not only PKA but also other signaling molecules to specific neuronal processes. By using transgenic mice expressing Ht31, a PKA anchoring blocking peptide, we previously showed that significantly reduced Ht31 expression in hippocampal area CA3 rescued deficits in a form LTP and spatial memory observed when Ht31 was highly expressed throughout hippocampal subregions. However, the subregion specific role of PKA anchoring in input-specific nature of LTP and memory formation is still not clear. Here, we adopted two-pathway synaptic tagging paradigm and contextual fear conditioning to further investigate the role of compartmentalized PKA signaling in synaptic plasticity and memory formation. We found that both strong-before-weak and weak-before-strong version of synaptic tagging, and contextual fear memory were impaired only when Ht31 was highly expressed throughout hippocampal subregions but not impaired when Ht31 expression was significantly suppressed in CA3. In addition, we found that forskolin, an adenylate cyclase activator, -induced LTP which relies on CA3 presynaptic neurotransmitter release was not affected only when Ht31 expression level was markedly reduced in CA3. Although postsynaptic PKA function in CA1 is important, these data suggest that presynaptic compartmentalized PKA signaling in CA3 is critical for hippocampal synaptic plasticity and memory formation.

Title: Impact of NMDA receptor overexpression on cerebellar Purkinje cell activity and motor learning

Authors: *M. SCHONEWILLE[1], E. GALLIANO[2], M. RUTTEMAN[2], M. BOCCHIO[2], D. JAARSMA[2], F. E. HOEBEEK[2], C. I. DE ZEEUW[2]

Abstract: A basic property of chemical synapses is their ability to modify themselves in response to certain stimulus patterns. This property, known as synaptic plasticity and predicted by Donald Hebb, is thought to be the cellular basis of learning and memory. Hebbian plasticity requires the existence of a coincident detector of pre- and post-synaptic activities, a role that the N-methyl-D-aspartate glutamate receptor (NMDAR) can fulfill.
Interestingly, at the main plastic site of one of the oldest learning circuits in the mammalian brain, the parallel fiber to Purkinje cell synapse (PF-PC) in the cerebellum, NMDAR are absent. Indeed, in Purkinje cells NMDAR are exclusively found facing the other glutamatergic input, i.e. the climbing fibers. However the PF-PC synapse is, as shown by a multitude of studies, plastic. One could therefore wonder what the introduction of functional NMDAR at the PF-PC synapse would imply in terms of synaptic plasticity and, eventually, behavioral learning.
To answer this question we overexpressed the NR2B subunit of the NMDA receptor selectively in murine cerebellar Purkinje cells using the Pcp-2/L7 promoter. Here we report the results from two independent mouse lines that showed normal growth, no sign of ataxia and no gross morphological abnormalities. Western blot analysis and electrophysiological characterization

confirmed respectively that both transgenic lines express significantly more NR2B protein and NMDA-mediated currents than their wild type littermates. Functionally, NR2B transgenic mice show normal motor behavior but impaired eye movement adaptation and synaptic plasticity. Together these data suggest a direct connection between abnormal NMDAR expression in Purkinje cells and impaired learning implying that, to guarantee proper learning, non-Hebbian forms of plasticity are essential.

Title: Calmodulin targeting regulates long-term potentiation

Authors: *L. ZHONG, N. GERGES
Cell Biology, Neurobio. and Anat., Med. Col. of Wisconsin, MILWAUKEE, WI

Abstract: Calcium entry and the subsequent activation of CaMKII trigger synaptic plasticity in many brain regions. The induction of long-term potentiation (LTP) in the CA1 region of the hippocampus requires a relatively high amount of calcium-calmodulin. This requirement is usually explained, based on in vitro and theoretical studies, by the low affinity of CaMKII for calmodulin. An alternative hypothesis, however, is that calmodulin is not randomly distributed within the spine and its targeting within spine regulates LTP. Using post-embedding immunogold electron microscopy, we show that calmodulin gold particles are not randomly distributed, but spatially organized in the spine. Neurogranin regulates calmodulin distribution such that its overexpression concentrates calmodulin closer to the plasma membrane, where a high level of CaMKII immunogold labeling is also found. The targeting of calmodulin by neurogranin is sufficient to lower the threshold for the induction of LTP. These findings help to understand the physiological role of calmodulin targeting within the spine in synaptic plasticity.

Title: Demyelination affects memory function.

Authors: *S. BALTAN, R. DUTTA, S. BRUNET, A. CHOMYK, G. KIDD, B. TRAPP
Dept. of Neurosciences, Cleveland Clin., Cleveland, OH

Abstract: Multiple sclerosis (MS) is an immune-mediated disease of the human central nervous system (CNS) that demyelinates white and grey matter. While neurological disability is diverse, demyelination of the hippocampus is likely to contribute to the cognitive dysfunction found in greater than 50% of MS patients. We recently reported extensive demyelination in MS hippocampus with minimal neuronal loss accompanied by significant decreases in synaptic density and genes associated with glutamate neurotransmission, memory and synaptic plasticity. To explore if loss of myelin can alter neuronal function, we have generated a mouse model with a combination of cuprizone and rapamycin (C/R) that lead to consistent hippocampal demyelination. Using this treatment paradigm, six (acute) and 12 week (chronic) of C/R administration reduced hippocampal myelin to 20% and to 5% of control levels, respectively. Spontaneous remyelination occurred after withdrawal of the combined treatment, and after 6 week of normal diet, remyelination reached to 80% in the acute model and to 63% of control levels in the chronic model. Demyelination correlated with decrease in key genes involved in AMPA mediated neurotransmission, synaptic plasticity and memory function. In addition, loss of hippocampal myelin was associated with a decrease in synaptic densities and major reorganization of synapses associated with CA1 hippocampal neurons as determined by 3D-EM analysis. Demyelination progressively impaired synaptic transmission leading to complete loss of long term potentiation (LTP) at 5 weeks in hippocampal slices. Chronic demyelination significantly impaired memory function assessed by Morris Water Maze. Interestingly, these changes were reversed by remyelination, establishing a role of myelin in controlling neuronal function. Modulation of synapses and remyelination is therefore an attractive therapeutic target for enhancing memory function.

Abstract: The post-synaptic density (PSD) is a region of concentrated proteins involved in the regulation of excitatory transmission and plasticity in dendritic spines. Glutamatergic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors mediate the majority of this transmission, and are essential for normal synaptic and cognitive function. A prominent molecule of the PSD, BRAG1 (Brefeldin A-Resistant Arf-GEF (Adenonise di-phosphate (ADP) ribosylating factor- guanine nucleotide exchange factor)-1) is implicated in X-linked mental retardation. Therefore, we have investigated the role of BRAG1 in synaptic function with electrophysiology and confocal imaging in rat organotypic hippocampal slice cultures. We report that BRAG1 is involved in the bidirectional regulation of AMPA receptors, suggesting an important role in synaptic function.

Title: Altered levels of endogenous proBDNF regulate hippocampal area CA1 synaptic plasticity

Authors: *L. C. HARTE-HARGROVE[1,2], J. YANG[3], T. MARINIC[3], J. J. LAFRANCOIS[1], B. L. HEMPSTEAD[3], H. E. SCHARFMAN[1,2]
[1]The Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY; [2]Child Psychiatry, Physiol. & Neuroscience, Psychiatry, NYU Langone Med. Ctr., New York, NY; [3]Dept. of Med., Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Brain-derived neurotrophic factor (BDNF) modulates hippocampal area CA1 synaptic plasticity including long-term potentiation (LTP) and long-term depression (LTD). The *bdnf* gene is translated as a precursor, proBDNF, that can be cleaved to mature BDNF (mBDNF). Importantly, mBDNF increases hippocampal LTP, whereas application of recombinant proBDNF can enhance LTD. This suggests that relative levels of mBDNF to proBDNF can alter synaptic plasticity. However these conclusions relied upon exogenously-applied proBDNF. Therefore, we examined the impact of endogenous proBDNF on synaptic plasticity in CA1. We generated a knock-in mouse in which one *bdnf* allele was replaced by cleavage resistant *probdnf*, leaving one normal allele (*probdnf*/+ mice). We also studied animals haploinsufficient for *bdnf* (*bdnf*+/-), and controls (*bdnf*+/+). We evaluated area CA1 field EPSPs (fEPSPs) in horizontal hippocampal slices (400 μm-thick) from 4-7 wk old mice. Slices were placed in an interface-style recording chamber and kept at 31-32°C in artificial cerebrospinal fluid (in mM: 126 NaCl, 4 KCl, 2.5 $CaCl_2$, 1.0 $MgSO_4$, 26 $NaHC0_3$, 1.25 NaH_2P0_4, 10 D-glucose). Standard recording procedures were used (Skucas et al., 2011). Following a stable baseline, theta burst stimulation (TBS; 10 bursts of 4 pulses at 100 Hz, 200 ms apart) was triggered. TBS was chosen because it elicits BDNF-dependent LTP. Although *bdnf*+/- mice had significantly reduced fEPSP slopes, indicating a deficit in basal transmission, *probdnf*/+ mice had the greatest deficits in basal transmission. Additionally, while *bdnf*+/+ mice showed LTP 60 minutes after TBS (132% ± 1.6; n=16 slices, 12 mice), *bdnf*+/- mice had neither LTP nor LTD (99% ± 4.5%; n=8 slices, 5 mice) and *probdnf*/+ mice showed LTD (71% ± 11.1; n=9 slices, 6 mice), suggesting that elevated levels of proBDNF have a substantially different effect on synaptic plasticity than reduced levels of mBDNF (due to haploinsufficiency of *bdnf*). The results indicate that levels of endogenous mBDNF and proBDNF can affect basal transmission and plasticity in area CA1. The deficits

may be relevant to cognitive impairments and psychiatric diseases in which BDNF levels have been suggested to play an important role.

Title: Shunted TrkB signaling leads to loss of striatal long term potentiation in Huntington's disease

Authors: *J. L. PLOTKIN[1], M. DAY[2], J. D. PETERSON[2], X. ZHONG[2], C. S. CHAN[2], E. ILLIJIC[2], D. J. SURMEIER[3]

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder profoundly impacting the major input nucleus of the basal ganglia, the striatum (caudate and putamen). Cognitive and behavioral deficits appear well before frank neuronal degeneration, as do overt abnormalities in striatal and cortical physiology. The integration and prioritization of cortical inputs to the basal ganglia is the charge of striatal spiny projection neurons (SPNs), but their nonlaminar structure and highly convergent afferents have made this an elusive process to study, both in normal and disease states. Here we show, using 2 photon uncaging of glutamate and a novel method to induce long term potentiation (LTP) at individual glutamatergic inputs, that a subset of SPN dendritic spines readily support LTP, and this process is attenuated in the BACHD and Q175 mouse models of HD. This LTP requires both NMDA receptors and BDNF activation of TrkB receptors. Importantly, we show that the loss of LTP in BACHD mice is not due to a loss of TrkB receptors, but rather inhibition of TrkB signaling through an upregulated phosphatase, suggesting a novel therapeutic target for this disorder.

Title: Effects of multiple isoflurane exposures on long term potentiation in the hippocampus

Authors: *R. LONG[1,2], E. PRAGER[2], R. KENNEALLY[2,3], M. BRAGA[2]
[1]Rockville, ; [2]Neurosci., Uniformed Services Univ., Bethesda, MD; [3]Walter Reed Natl. Military Med. Ctr., Bethesda, MD

Abstract: Service Members wounded in action during Operations Iraqi Freedom and Enduring Freedom, or New Dawn, require multiple administrations of general anesthetics in a short period of time after exposure to a traumatic brain injury (TBI). While the deleterious effects of TBI on cognitive function are the subject of intense scientific investigations, little is known about the effects of multiple exposures to general anesthetics in the brain. By using electrophysiological techniques, we examined the effects of repeated exposures to isoflurane on the induction and maintenance of long-term potentiation (LTP) in the rat hippocampus. Male Sprague-Dawley rats, ages 7-8 weeks (n=5) and 13-14 weeks (n=5), were anesthetized with 1.5% isoflurane and 100% oxygen for one hour every other day, for a total of three exposures in one week. 24 hours or 7 days after the final exposure, CA1 hippocampal field recordings were obtained. 24h after the final anesthetic, hippocampal LTP was significantly increased compared with naïve controls ($p=0.007$), while at 7 days after the final session, hippocampal LTP was inhibited compared to baseline recordings ($p=0.013$). These data suggest that multiple exposures to general anesthesia may produce long-term adverse effects on hippocampal-dependent learning and memory functions. Continued evaluation of the effects of repeated isoflurane exposure will provide insight for the development of rehabilitative medicine strategies.

Title: Reduced D-serine levels in the nucleus accumbens of cocaine-treated rats hinder the induction of NMDA-dependent synaptic plasticity

Authors: L. CURCIO[1], L. LEONE[1], M. V. PODDA[1], R. PIACENTINI[1], P. CAPPELLETTI[2], S. SACCHI[2], L. POLLEGIONI[2], C. GRASSI[1], *M. D'ASCENZO[1]
[1]Inst. of Human Physiol., Catholic Univ., Rome, Italy; [2]Dept. of Biotech. and Life Sci., Univ. of Insubria, Varese, Italy

Abstract: Recent data have shown that D-serine is a physiologically relevant glycine-site ligand of NMDAR in several brain areas. Aim of the present study was to investigate the potential involvement of D-serine signaling in cocaine-induced changes in NMDAR-dependent synaptic plasticity in the nucleus accumbens (NAc). Analysis of the peak amplitudes of AMPAR- and NMDAR-mediated EPSCs revealed a significantly increased AMPA/NMDA ratio in rat slices treated with the selective D-serine degrading enzyme DAAO respect to control slices (6.0 ± 1.1 vs. 1.3 ± 0.1; n=10). Moreover, D-serine degradation markedly reduced the amplitude of NMDAR-dependent LTP and LTD (-92.2%, and -90.2%, respectively). The results indicate that D-serine is the endogenous coagonist of synaptic NMDAR in the NAc, where its presence is essential for NMDAR-dependent synaptic plasticity. We then compared the amplitude of LTP and LTD in slices obtained from cocaine- and saline-treated rats in the absence or in the presence of saturating levels of exogenous D-serine (100 μM). The amplitudes of LTP and LTD were markedly reduced in slices from cocaine-treated animals (-55.3% and -80.4%; respectively), but were completely restored to saline values when slices were perfused with exogenous D-serine thus suggesting that cocaine treatment of rats reduces D-serine levels in the NAc. Exogenous d-serine increased NMDAR currents in slices from cocaine-treated rats to a greater extent than that observed in the saline-treated rats (+196% v.s +78%). This observation further support our hypothesis and prompted us to measure D-serine concentrations in the NAc slices from cocaine- and saline-treated rats, by high performance liquid chromatography (HPLC). This set of experiments revealed that the amount of D-serine decreased significantly from 4.6 ± 0.9 pmol/μg of protein (saline-treated rats) to 2.7 ± 0.4 pmol/μg of protein (cocaine-treated rats). To investigate whether the reduced D-serine levels in the NAc core was due to changes in the expression of the enzymes responsible for its biosynthesis and/or degradation, we performed real time RT-qPCR and Western blot analyses of NAc extracts. DAAO mRNA and protein levels were significantly increased in the NAc core of cocaine treated rats (+68%; and +195%; respectively). On the other hand a significant decrease in SR protein levels (-50.6%) was observed, although no difference in the corresponding mRNA transcript level was detected. Taken together these data suggest an important role for D-serine signaling in the NAc as molecular correlate for cocaine-induced impairment of NMDAR-dependent synaptic plasticity.

Title: Modulation of plasticity with low amplitude electric fields in rat hippocampal slices.

Authors: *B. LAFON, D. REATO, A. RAHMAN, M. BIKSON, L. PARRA
City Col. of New York, New York, NY

Abstract: Low amplitude electric fields are known to modulate ongoing neural activity as well as induce prolonged excitability changes lasting several minutes and up to an hour. Animal and human studies seeking to explain the effects of weak field stimulation have thus far identified immediate effects on neural activity such as acutely altered spike timing and changes in excitability that may result in network entrainment and changes in firing rate. However, demonstrating the physiologic underpinning of the long term plastic effects has remained elusive.

Here we are particularly interested in the effects of slow-oscillating stimulation during sleep which were shown to boost the consolidation of hippocampus-dependent declarative memory. How synaptic connections are modified resulting in a memory improvement is still unknown. Currently, two main complementary hypotheses exist regarding consolidation of memory during sleep. The synaptic homeostasis hypothesis conjunctures that consolidation is in part a result of synaptic downscaling that improves the signal-to-noise ratio for all synapses that were potentiated during prior waking experiences. The active system consolidation hypothesis proposes an active consolidation process where learning-specific synaptic connections are strengthened by means of increased plasticity-related immediate early gene transcription and induction of LTP.

Slow-oscillating stimulation has been linked to synaptic homeostasis by an effect on the homeostatic downscaling of endogenous slow-waves during sleep. However, the mechanisms by which this low-amplitude stimulation might be modulating LTP processes related to the potentiation of learning related synapses has not yet been studied. Previous studies show that

electrical stimulation coupled with ongoing activity in the brain induces plasticity, here we will focus on the modulation of LTP processes while applying acutely several low-amplitude field configurations. Thus linking the long-term behavioral effects with acute electrical stimulation.

Title: Chronic unpredictable stress attenuates synaptic plasticity in the dentate gyrus and increases the incidence of depressive-like behaviours

Authors: *E. R. WHITE[1], P. S. BROCARDO[1], D. F. HAWLEY[2], J. LEIGH LEASURE[2], B. R. CHRISTIE[1]

Abstract: Chronic stress is an epidemic in today's society; approximately 6.5 million adult Canadians experience high or extreme stress most days of their lives. One region of the brain particularly affected by chronic unpredictable stress (CUS) is the hippocampus. The hippocampus is not a uniform structure, as dorsal regions may be more involved in spatial function with ventral more involved in affect. Previous studies have found decreased survival of progenitor cells in the ventral, but not the dorsal, hippocampus. The purpose of this study was to determine if CUS preferentially reduced synaptic plasticity in the ventral dentate gyrus (DG). Twenty-four adult male Long-Evans rats were divided into control or stressed groups. For 14 days, stressed animals were subjected daily to an unpredictable schedule of ethologically relevant stressors, such as altered light cycle, predator sounds, and damp bedding. Twenty-four hours following the last stressor, sucrose preference and splash tests were performed. Both tests indicated that animals were exhibiting signs of stress. CUS animals exhibited a reduction in sucrose preference, and increased latency to start grooming coupled with diminished time spent grooming when compared to controls during the splash test. Immediately after behavioural testing, animals were sacrificed for in vitro electrophysiology field recordings in which long-term potentiation (LTP) was elicited in the dorsal and ventral DG. In contrast to a region specific

effect for neurogenesis, synaptic plasticity was attenuated in both ventral and dorsal slices following CUS.

Title: Methylphenidate influence over *in vivo* hippocampal plasticity underlying memory

Authors: D. JENSON[1], A. ACEVEDO-RODRIGUEZ[2], J. TANG[2], *J. A. DANI[2]
[1]Baylor Col. of Med., Houston, TX; [2]Dept Neurosci., Baylor Col. of Med., HOUSTON, TX

Abstract: Attention-Deficit Hyperactive Disorder (ADHD) is the most commonly studied and diagnosed psychiatric disorder in children. Methylphenidate (MPH, e.g., Ritalin) is the most commonly prescribed treatment for ADHD, and it has been used for decades to treat ADHD, but little is known about its therapeutic mechanisms.
The hippocampus is a center for learning and memory, and synaptic plasticity is a measurable underlying mechanism for memory. This project examines the effects of MPH on synaptic plasticity in the hippocampus that correlates with and may contribute to learning and memory. Our hypothesis is that MPH will affect synaptic plasticity in the hippocampus that underlies learning, and the influence of MPH will arise from its ability to boost catecholamine signaling. The object of this proposal is to determine the effects of MPH on synaptic plasticity in the hippocampus of awake animals, and to more clearly elucidate its mechanism of action in the hippocampus.
We measure synaptic plasticity in response to MPH in the perforant path to dentate gyrus pathway in the hippocampus by recording field potentials with permanently implanted electrodes in freely moving mice. When weak theta burst stimulation was applied along the perforant pathway, it did not produce synaptic change. However, when the same stimulation was applied along with MPH (5 mg/kg), then the stimulation produced long-term potentiation (LTP) of 64 ± 18 % ($n=6$, $p<0.01$). These in vivo recordings offer a highly precise measurement of synaptic

transmission, while preserving the overall circuitry and neurotransmitter systems that we ultimately wish to understand.

Title: Astrocytes mediate nucleus basalis enabled, orientation stimulus specific plasticity in V1

Authors: N. CHEN[1], H. SUGIHARA[2], J. SHARMA[2], G. PEREA[2], J. PETRAVICZ[2], C. LE[2], *M. SUR[1]
[1]Brain & Cognitive Sci., MIT, CAMBRIDGE, MA; [2]MIT, Cambridge, MA

Abstract: While sensory experience associated with nucleus basalis (NB) driven, cholinergic activation of the cortex has been shown to instruct cortical plasticity, little is known about the underlying cellular mechanisms. To understand how cortical responses and representations can be altered by experience during cholinergic modulation, it is critical to identify the circuit elements involved and elucidate how their interactions can alter cortical network dynamics. In this work, we show that electrical stimulation of NB, paired with visual stimulation in vivo, can induce significant potentiation of visual responses in excitatory neurons recorded by cell-attached patch in mouse primary visual cortex (V1). We further demonstrate with in vivo two-photon calcium imaging, ex vivo calcium imaging and whole-cell recordings that this pairing induced potentiation is mediated by direct cholinergic activation of V1 astrocytes via muscarinic acetylcholine receptors. The astrocyte-mediated potentiation is stimulus specific, as pairing NB stimulation with a specific visual orientation reveals a highly selective potentiation of responses to the paired orientation compared to unpaired orientations. Collectively, these findings reveal a novel and surprising role for astrocytes in NB-induced stimulus-specifc plasticity in the cerebral

cortex and suggest an intimate organization of astrocytes with the synapses that convey and generate orientation specific responses.

Title: Regulation of synaptic plasticity by the partnership of proheparanase with peri-synaptic heparan sulfate proteoglycan and AMPA-type glutamate receptor

Authors: *C.-W. MA[1,2], Y. L. LAM[2], W. C. CHAM[2], Y. S. CHAN[1], D. K. Y. SHUM[2]
[1]Dept. of Physiol., [2]Dept. of Biochem., The Univ. of Hong Kong, Hong Kong, China

Abstract: Perineuronal heparan sulfates (HS) have been implicated in controlling the open-state of AMPA-type glutamate receptors (AMPARs) which govern excitatory synaptic transmission in the hippocampus. We hypothesize that neuronal mechanisms modulate peri-synaptic HS level and as a result regulate synaptic function. Our finding of neuronal heparanase expression in adult rats led us to test if neuronal heparanase is secreted to act on perineuronal HS, thereby contributing to synaptic plasticity. Following phorbol ester stimulation of hippocampal neurons in culture, Western blot analysis of the secreted product revealed proheparanase but not the active heparanase. Synaptosomes prepared from phorbol ester-treated cortex slices were enriched in proheparanase; co-immunoprecipitation studies further showed association of AMPAR subunits (GluA1 and GluA2/3) with both syndecan-3 (transmembrane HS-proteoglycan) and proheparanase, suggesting their clustering as a functional complex. Treatment of hippocampal neuron cultures with recombinant proheparanase triggered internalization of proheparanase, perineuronal HS-proteoglycans and AMPARs. Heparitinase pre-treated hippocampal neuron cultures showed reduced proheparanase-induced internalization of AMPARs, suggesting that proheparanase binds to syndecan-3 via the HS moiety. Consistent with these findings, treatment of hippocampal slices with exogenous proheparanase resulted in declines in both basal synaptic strength and LTP. Proheparanase treatment also prevented glutamate-induced calcium influx of the hippocampal neurons in culture. These results reveal a novel role of neuronal proheparanase

in regulating synaptic plasticity by resetting AMPARs and perineuronal HS levels at the synapse. [*Supported by HKRGC 774608*]

Title: Role of thalamic vs. cortical NMDA receptors in LTP in the primary visual cortex: Shift to a cortical mechanism by visual discrimination training of adult rats

Authors: *A. M. HAGER, H. C. DRINGENBERG
Queens Univ., Kingston, ON, Canada

Abstract: Synaptic plasticity (long-term potentiation, LTP) plays an important role in processes of learning and memory formation and several studies now have identified LTP-like changes at central synapses following various types of learning experiences. The thalamocortical projections from the lateral geniculate nucleus (LGN) to the primary visual cortex (V1) have been shown to reliably produce LTP in adult rats. Here, we examined the role of N-methyl-D-aspartate (NMDA) receptors in the LGN and V1 for LTP in this fiber system. Adult, urethane anesthetized rats exhibited reliable LTP of field post-synaptic potentials (fPSPs) in V1 following theta-burst stimulation of the LGN. Local application of the NMDA receptor antagonist DL-2-amino-5-phosphonovaleric acid (APV; 10 mM, applied by reverse microdialysis) in the LGN blocked LTP induction, while cortical application was ineffective. Thus, thalamic NMDA receptors appear to be critical for the induction of this type of thalamocortical plasticity.
In a second set of experiments, behavioral (visual discrimination) training was carried out prior to LTP induction. Interestingly, trained rats displayed significantly greater levels of LTP (~50%) relative to naïve or swim-control animals (~25% LTP), indicative of a metaplastic increase in the modification range of V1 synapses. This enhanced potentiation in trained rats was reversed by application of APV to either the LGN or V1, resulting in naïve-like levels of LTP in trained rats (~25% LTP). Thus, visual training can result in the appearance of a novel, cortical locus to induce robust LTP even in the absence of thalamic NMDA receptor contributions. These data are consistent with previous evidence, showing that visual training leads to a metaplastic increase of

LTP in V1 that involves NR2B subunits of NMDA receptors.
In summary, plasticity in the rodent thalamocortical visual system is strongly influenced by experience-dependent factors: naïve LTP depends on thalamic NMDA receptors, while visually trained animals are able to recruit both thalamic and cortical NMDA mechanisms to express LTP. Thus, future work examining anatomically distributed networks will be necessary to further characterize plasticity, particularly for neural circuits shaped by training and other behavioral experiences.

Title: Functionality of paired associative stimulation when the soleus muscle is targeted

Authors: *S. M. KUMPULAINEN[1], N. MRACHACZ-KERSTING[1], M. VOIGT[1], A.-M. ALEXANDROU[2], J. AVELA[2]

Abstract: There are several studies showing that paired associative stimulation (PAS) can induce local changes in excitability of cortical projections to the target muscle. However, these studies have not examined the effect on functionality in a related motor performance. The purpose of this study was to measure the functionality of PAS-induced effects when the soleus muscle (SOL) is targeted. Subjects sat on a custom built ankle dynamometer (hip, 110°; knee, 180°; ankle, 90°) with their right foot resting on a pedal. Transcranial magnetic stimulation (TMS) was used to measure motor-evoked potentials (MEPs) of SOL before and following PAS. PAS-intervention consisted of 200 paired stimuli of tibial nerve electrical stimulation and TMS over the soleus area of motor cortex. To identify potential changes in spinal excitability, SOL short latency stretch reflexes (SLR) were elicited with perturbations induced by the ankle dynamometer. Functionality was measured with three different isometric plantar-flexor motor tasks, which assessed rate of force development (RFD), reaction time and accuracy of force control. SLR measurements and the motor tasks were also performed in a control group. Depending of the PAS-effect, the 24 subjects were divided into a facilitation group (16), where there was an increase in the MEP amplitudes (81 ± 92 %) following PAS and an inhibition group

(8), where there was a decrease in the MEP amplitudes (-31 ± 17 %). SLR remained unchanged after the intervention in all groups suggesting no changes in the excitability at the spinal level. Reaction time shortened and accuracy of force control improved significantly in the facilitation group and RFD decreased significantly in the inhibition group ($P < 0.05$). There were no changes in the motor performance in the control group. Our results demonstrate that the leg motor performance of healthy subjects can be enhanced by facilitative PAS - intervention.

Title: Neuropsin-dependent synaptic plasticity in the hippocampal CA1 field of freely moving mice.

Authors: *Y. ISHIKAWA, H. YAMASHITA, S. SHIOSAKA
NAIST, Nara, Japan

Abstract: Long-term potentiation (LTP) is supposed to be a cellular mechanism involved in memory formation. Similar to distinct types of memory formation, LTP can be separated into a protein synthesis-independent early phase (early-LTP) and a protein synthesis-dependent late phase (late-LTP). An important question is whether the transformation from early- into late-LTP can be elicited by behavioral conditions such as the attention to novel events.
In our previous study, we found that synaptic plasticity in the hippocampal Schaffer collateral pathway depended on neuropsin (kallikrein-related peptidase 8 or KLK8), a plasticity-related extracellular protease in acute hippocampal slices and in anaesthetized mice. However, neuropsin dependent synaptic plasticity in freely moving mice remains poorly understood. Therefore, we investigated the neuropsin-dependent effect of early-LTP and novelty-exploration with early-LTP in the hippocampal CA1 of freely moving mice. In the present study, we investigated how neuropsin participates in synaptic plasticity in the hippocampal CA1 of freely moving mice. We found that neuropsin-knockout mice were significantly impaired in early-LTP induced by a single tetanus.

Title: The role of the GluN2A subunit of the NMDA receptor in synaptic plasticity and spatial pattern separation in the dentate gyrus.

Authors: *T. S. KANNANGARA[1,3], B. D. EADIE[2], C. A. BOSTROM[2], P. S. BROCARDO[2], B. R. CHRISTIE[2,3]

Abstract: The different secondary subunits of the *N*-methyl-D-aspartate (NMDA) receptor each convey unique biophysical properties to the receptor complex, and may be key in determining the functional role played by NMDA receptors. In the hippocampus, the GluN2A and GluN2B subunits are particularly abundant, however their exact roles in synaptic plasticity and behaviour remain controversial. Here we show that mice lacking GluN2A subunits exhibit a significant shift in the ratio of NMDA to AMPA (α-amino-3- hydroxy-5-methyl-4-isoxazolepropionic acid) current in granule cells of the dentate gyrus, without impacting mature dendritic morphology. These animals also show significant impairments in both long-term potentiation (LTP) and long-term depression (LTD) of synaptic efficacy in the dentate gyrus. These deficits are not apparent in pyramidal cells of the CA1 subfield. In addition to this decrease in bidirectional synaptic plasticity in the dentate gyrus, GluN2A$^{-/-}$ animals show impaired performance on spatial pattern separation tasks that have been reported to be dentate gyrus-specific. In contrast, GluN2A$^{-/-}$ mice show no deficit in temporal pattern separation, a process associated with CA1 functioning. Our data indicates that the GluN2A subunit may play an important role in synaptic and behavioural plasticity in the dentate gyrus.

Title: Presynaptic netrin-G subtypes differentially control synaptic plasticity and behavior in mice

Authors: *H. MATSUKAWA[1], H. GOTO[1], R. LUJÁN[2], S. AKIYOSHI-NISHIMURA[1], Q. ZHANG[1], K. YAGUCHI[1], T. HASHIKAWA[1], R. SHIGEMOTO[3], S. ITOHARA[1]
[1]Brain Sci. Inst., Wako, Japan; [2]Univ. Castilla-La Mancha, Albacete, Spain; [3]NIPS, Okazaki, Japan

Abstract: Netrin-G1 and netrin-G2, are vertebrate-specific, GPI-anchored membrane proteins of the UNC-6/netrin family. They are expressed on the axons of distinct neuronal circuits within the brain. The pattern of this expression determines the distribution of their dedicated receptors, NGL-1 and NGL-2, within sub-dendritic segments of target neurons, in a cortical layer-specific manner (Akiyoshi-Nishimura et al., PNAS, 2007). The physiological roles of these trans-neuronal interactions, however, are poorly understood. Here, we performed electron microscopy and electrophysiological analysis on the hippocampus, a structure where netrin-G1/NGL-1 and netrin-G2/NGL-2 interactions occur along the distal temporoammonic pathway (TA-CA1) and the proximal Schaffer collateral pathway (SC-CA1), respectively. Immunostaining using antibodies against each netrin-G and its receptor, revealed that netrin G localized to excitatory presynaptic membranes, while receptors localized to postsynaptic membranes of selected pathways. Mice with deletions of either netrin-G1 or netrin-G2 showed opposing alterations in long-term and post-tetanic potentiation. Netrin-G1 knock-out (KO) mice showed attenuated TA-CA1 synaptic plasticity, while netrin-G2 KO mice showed augmented SC-CA1 synaptic plasticity. Furthermore, phorbol-ester induced potentiation of transmitter release was significantly reduced at the TA-CA1 synapse of netrin-G1 KO mice, but normal at the SC-CA1 synapse of netrin-G2 KO mice. This effect was indistinguishable between netrin-G1 KO and wild-type mice, in the presence of protein kinase C inhibitor. These results suggest that

presynaptic netrin-G subtypes play differential modulatory roles in glutamate release, via distinct biochemical pathways. In addition, we characterized the phenotypes of these KO mice in a wide range of behavioral tests. Netrin-G1 KO mice exhibited abnormalities in the fear freezing response, anxiety, locomotion and impulse control, whereas netrin-G2 KO mice showed abnormalities in spatial reference and working memory, procedural learning, anxiety, visual acuity, hearing and motor coordination. Interestingly, there was little overlap in phenotypes between the sets of mutants, reflecting the differential expression pattern of the two genes. Taken together, these findings indicate that trans-synaptic netrin-G/NGL interactions play important roles in modulating synaptic efficacy of specific neuronal circuits, as well as behavioral output.

Title: Recurrent apnea disrupts long-term potentiation (LTP) in the hippocampus in *in vivo* rats

Authors: S. J. FUNG[1,2], M. XI[1,2], *V. B. FENIK[3], J. LOPATTO[1,2], M. H. CHASE[1,2,4]

Abstract: Cognitive impairments, which commonly occur in humans with obstructive sleep apnea (OSA), are also present when animals are subjected to recurrent periods of apnea. Behavioral studies have demonstrated that rats that are exposed to chronic episodic hypoxia are deficient in Morris water maze learning tests. Since hippocampal long-term potentiation (LTP) is recognized as an important cellular substrate for learning and memory, we hypothesize that recurrent apnea reduces LTP in a monosynaptic excitatory (CA3-CA1) pathway in the hippocampus that has been shown to mediate the processing of cognitive information.
To examine this hypothesis, adult rats, which were anesthetized with α-chloralose and

immobilized with Flaxedil, were subjected to recurrent episodes of apnea (via ventilatory arrest). During each apneic episode, when the SpO2 was desaturated to 60%, re-ventilation was initiated until a baseline level of oxygen saturation (95%) was achieved. Following a 2 hr period of recurrent apnea, CA3 was stimulated and a baseline field excitatory postsynaptic potential (fEPSP) was recorded from CA1 5 min prior to the initiation of LTP. A high-frequency stimulation (400 Hz, 2 s duration, 800 pulses, 0.2 ms pulse width) paradigm was used to induce LTP in the CA1 fEPSP. LTP was then monitored for a period of 60 min. In control animals, LTP was recorded for 60 min while the animals were respired at normal levels of oxygen saturation. In control (normoxic) rats, LTP (220% of baseline fEPSP) was observed immediately after stimulation; thereafter, LTP remained at 180%. In apneic rats, LTP was significantly reduced compared with the response in normoxic animals. It was 130% initially and 125% of its baseline level during the recording period. We conclude that recurrent episodes of apnea have deleterious effects on long-term synaptic plasticity in a hippocampal pathway that is involved in the processing of cognitive information. Title: Low frequency stimulation induced long term potentiation at the accessory olfactory to medial amygdala synapse in Anurans.

Authors: *G. DEROSENROLL, K. DELANEY
Biol., Univ. of Victoria, Victoria, BC, Canada

Abstract: Long term potentiation (LTP), an activity-based long-lasting enhancement of the synaptic connectivity between neurons, currently stands as one of the best physiological models for learning in the brain. NMDA glutamate receptor-dependent high frequency stimulation-induced LTP is the most studied form of LTP in the CNS. We made use of an en bloc preparation of the amphibian Rana catesbiana brain that maintains the integrity of the

telencephalon in order to study another form of LTP in the amygdala, which receives direct inputs from many brain areas including the main and accessory olfactory bulbs. Extracellular field recordings reveal a form of LTP in the medial amygdala, induced by repetitive low frequency stimulation of the accessory olfactory tract (AOT) comprised of the axons of mitral cells projecting from the accessory olfactory bulb. Field potential amplitude was tested every 20 seconds with a single stimulation of the AOT that evoked 30% of maximum field. Conditioning trains of 1Hz (900 pulses) or 5Hz (5 x 25 pulses; 15s intervals) delivered to the AOT induced up to threefold increase of field strength that persisted for at least three hours. Additionally, 5Hz conditioning yields a transient post-tetanic potentiation up to sixfold over baseline that decays to the sustained LTP level over the course of 50 minutes. Since the accessory olfactory bulb, receives primary sensory information from the vomeronasal organ, and its target, the amygdala, plays an important role in the expression of mammalian fear the phenomenon reported here could represent a sensitization to predator odours or a mechanism to enhance detection of behaviourally relevant odours that are persistent in the environment.

Title: Understanding and optimizing vagus nerve stimulation directed cortical plasticity

Authors: *M. BORLAND, W. A. VRANA, K. C. RAHEBI, N. A. MORENO, B. R. HEATH, M. M. PANTALIA, R. E. BABU, S. ISLAM, M. P. KILGARD
Univ. of Texas At Dallas, Dallas, TX

Abstract: Abstract Vagus nerve stimulation (VNS) is a safe and effective treatment for refractory epilepsy. Map plasticity can be directed in primary auditory or primary motor cortex by pairing a tone or a movement with a brief bursts of VNS. VNS-directed plasticity has been shown to be highly effective in treating an animal model of tinnitus (Engineer et al., 2011). Our VNS-tone pairing paradigm requires one hundred times less VNS than is used to treat epilepsy. The mechanisms by which vagus nerve stimulation directs neural plasticity are not clear and the optimal stimulation parameters to direct plasticity are not known. Earlier studies had suggested that the effect of VNS is an inverted-U function of current intensity with a peak at 0.4 mA. Preliminary analysis of our modified paradigm using 0.5 second bursts of VNS instead of 30

second trains suggests that 0.8 mA and 1.2 mA VNS result in equivalent cortical map plasticity, while 0.4 mA VNS does not generate detectable plasticity. Map plasticity is reduced when the interval between VNS-tone pairing events is decreased from 30 to 8 seconds. Based on earlier evidence that locus coeruleus is required for the effects of VNS, we have injected rats with DSP-4 to destroy the central noradrenergic system and determine whether release of norepinephrine is required for VNS-directed map plasticity. Results from these studies will be used to inform the clinical optimization of VNS-event pairing as a treatment for tinnitus and other neurological disorders.

Title: Cerebellar mechanisms underlying habituation of the acoustic startle response

Authors: X. CHEN[1], H. ADELSBERGER[2], A. STROH[2], C. RUEHLMANN[2], M. BRILL[2], T. MISGELD[2], *A. A. KONNERTH[2]
[1]Brain Res. Center, TMMU, Chongquing, China; [2]Tech. Univ. Munich, Munich, Germany

Abstract: Habituation, representing the gradual reduction of the organism's response after repeated sensory stimulation, is an important and universal feature in the animal kingdom, which is relevant for the adaption to the surrounding environment (Thompson and Spencer, 1966; Groves and Thompson, 1970). Habituation of the acoustic startle response, one of the most commonly used models for studying this type of simple learning in mammals (Thorpe, 1956), has been considered to involve the cerebellar vermis (Leaton and Supple, 1986; Lopiano et al., 1990; Timmann et al., 1998; Frings et al., 2006). However, the precise identification of neural locus and underlying cellular mechanisms remained unclear. Here by using two-photon imaging-based in vivo electrophysiological recordings, we find that repeated sound stimulation induces both behavioural habituation of the acoustic startle response as well as a reduction of sound-evoked excitatory postsynaptic potentials (EPSPs) and simple spike firing in Purkinje neurons of the mouse cerebellar vermis. The behavioural habituation and the reduction of EPSPs show highly similar time courses. Blocking GABA-A receptor-mediated synaptic inhibition by

pharmacological or molecular manipulations blocks both the reduction of EPSPs and behavioural habituation. This suggests that activity-dependent potentiation of synaptic inhibition in Purkinje neurons, a process that was previously termed rebound potentiation (Kano et al., Nature, 1992), is essential for the habituation of the acoustic startle response. Finally, optogenetically-induced inhibition in Purkinje neurons artificially causes habituation of the acoustic startle response. Together, our result identify essential cellular and circuit mechanisms underlying the habituation of the acoustic startle response in mammals.

Title: Effects of phosphodiesterase 9 inhibition on synaptic transmission and neurodegeneration

Authors: *A. I. PARACHIKOVA[1], K. PEDERSEN[1], L. GLASDAM JENSEN[1], C. YANG[2], H. SINDAL JENSEN[1], N. SVENSTRUP[1], N. PLATH[1]
[1]Lundbeck A/S, Valby, Denmark; [2]Shanghai Chempartner Co. Ltd., Shanghai, China

Abstract: Cyclic nucleotides have long been recognized to play a crucial role in regulating synaptic plasticity. Increased levels of cAMP as well as cGMP have been associated with improved memory performance as well as amelioration of experimentally induced deficits in long term potentiation in rodents. Consequently, phosphodiesterase inhibitors, which lead to an increase in cAMP and/or cGMP levels have been viewed as potential drugs for increasing cognitive functioning. The PDE superfamily of enzymes consists of 11 members; the cGMP selective PDE9 is characterized by widespread expression in the brain, albeit at low levels, which could be offset by a particularly low Km for cGMP. Previously, PDE9 inhibition has been demonstrated to reverse learning and memory deficits observed in various models of pharmacological disruptors. The pro-cognitive potential of PDE9 inhibitors has led to the hypothesis that inhibition of this enzyme could be beneficial for the symptomatic treatment of Alzheimer's disease (AD). To date, no evidence however has been presented linking PDE9 inhibition to the underlying pathological hallmarks of the disease.
We have investigated the role of PDE9 inhibition with particular focus on the deficits associated with AD pathogenesis. The pathway resulting in cGMP production has been linked to β-amyloid

and the downstream alterations in neuroinflammation. Based on these data, we employed an APP transgenic model of the disease and evaluated the effect of PDE9 inhibition at both a behavioral and purely mechanistic level. Behavioral characterization of PDE9 inhibition demonstrates reversal of cognitive deficits in the APP transgenic mouse model of AD. Furthermore, we examined the mechanism underlying the amelioration of synaptic functioning by PDE9 inhibition by addressing basic and advanced properties of spontaneous and evoked synaptic transmission.

Title: Sex difference of the effect of neonatal social isolation on experience driven synaptic delivery of AMPA receptors in rat barrel cortex

Authors: *H. TADA, K. SUYAMA, T. TAKAHASHI
Yokohama City Univ., Yokohama, Japan

Abstract: Although sex differences of the response to stress have been well known, molecular mechanisms are still poorly understood. Here we show that neonatal social isolation disrupts experience-driven delivery of GluR1 containing AMPA receptors to synapse in barrel cortex of males but not females. Furthermore, we found that injection of glucocorticoid disrupts experience dependent synaptic GluR1 trafficking in the barrel cortex of male but not female rats. Moreover, we showed that disruption of GluR1 trafficking with social isolation was not prevented in masuculinized female rats. Our findings suggested that female rats could have molecular machinery which protects social isolation stress induced disruption of synaptic AMPA receptors delivery.

Title: Developmental progression of pyramidal neuron excitability and dopamine modulation in PFC

Authors: *S. C. BARRETT[1,2], J. CHANDLER[2], H. TRANTHAM-DAVIDSON[2]
[1]Charleston, SC; [2]Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: The dopaminergic innervation of the prefrontal cortex (PFC) is highly plastic from birth through early adulthood; changes have been observed in dopamine (DA) receptor expression (Tarazi and Baldessarini, 2000) and activation (Tseng and O'Donnell, 2007). However, little is known about specific changes in D2 and D4 receptor function during this phase. Understanding how the DA system matures through development will help identify novel pharmacological targets to treat a variety of neurological disorders including schizophrenia, ADHD, and addiction. Preliminary studies indicate that there is a progressive increase in pyramidal neuron excitability and a concomitant decrease in baseline spike duration in cortical layer V in the PFC through early development (post-natal days 14-35) in male Long-Evans rats. This observation may reflect a developmental change of specific potassium channels that mediate neuronal excitation in this population of neurons. Additionally, D2 receptor stimulation in the same cellular population resulted in a progressive increase in firing rate throughout the same developmental period. Future studies will further explore the cellular mechanisms mediating these developmental changes in pyramidal neurons as well as changes in D2 and D4 receptor modulation of cortical activity. These findings will provide a detailed understanding of the developmental profile of pyramidal activity, which will contribute to our understanding of how this profile is disrupted in disorders of cognition and perhaps lead to better treatment strategies.

Title: Neural field theory of calcium dependent plasticity: Prediction and application to transcranial magnetic stimulation

Authors: *P. K. FUNG[1,2], P. A. ROBINSON[2], C. KERR[2]
[1]Complex Systems, Sydney, Australia; [2]Complex Systems, Sch. of Physics, Univ. of Sydney, Sydney, Australia

Abstract: Current theoretical knowledge of system-level synaptic plasticity is limited, partly because of the relatively rare in vivo, system-level plasticity experiments. Transcranial magnetic stimulation (TMS) is a noninvasive brain stimulation technique that induces system-level plasticity, but our understanding of TMS is limited. We propose a system-level plasticity model that predicts TMS signatures, thereby partially verify our theory, and gain an understanding of TMS.

We formulate our system-level plasticity model by incorporating calcium dependent plasticity (CaDP), a physiologically realistic microscopic plasticity mechanism into a meso- to macroscopic neural field theory, and explore system-level CaDP. We explore how large-scale neural activity leads to calcium influx, which induces system-level plasticity. In particular, we model the cortical plasticity response due to different TMS protocols, and match them with experimental results. This theory predicts various existing TMS experimental signatures, plus additional predictions subject to experimental verification. Predictions of this model includes the system-level, time-asymmetric plasticity window induced by paired associative stimulation, and the frequency dependence of TMS: that low frequency TMS induces depression, whereas high frequency TMS induces potentiation.

Our work thus allows understanding and promises future optimization of TMS. The verification of our work also provides partial verification of the neural field theory and calcium dependent plasticity. Therefore, this work is of interest to both theorists and experimentalists in the mechanism of synaptic plasticity and the scientific and medical aspects of TMS.

Title: Diabetes onset influences hippocampal synaptic plasticity in streptozotocin-treated rats

Authors: *S. SASAKI-HAMADA, H. SACAI, J.-I. OKA
Pharmacol., Tokyo Univ. of Sci., Chiba, Japan

Abstract: Children with type 1 diabetes mellitus (DM) are at risk of developing cognitive difficulties. Although when the diabetes begins influences these cognitive difficulties, synaptic properties related to the age of onset remain unknown. Here we showed that synaptic plasticity including long-term potentiation (LTP) or long-term depression (LTD), and excitatory synaptic transmission at Schaffer collateral-CA1 (SC-CA1) synapses in hippocampal slices were affected by age of onset in rats with streptozotocin-induced diabetes (STZ-rats), compared with age-matched control rats. In young adult-onset STZ-rats, LTP was impaired and the ratio of AMPA receptor-mediated EPSCs relative to NMDA receptor-mediated EPSCs (the AMPA/NMDA ratio) decreased, whereas LTD was impaired and both AMPA receptor-mediated and NMDA receptor-mediated EPSCs increased in juvenile-onset STZ-rats. These results suggest that the pathophysiology of diabetes-induced cognitive difficulties varies with the age of diabetes onset.

Title: Neural plasticity in injured spinal cord

Authors: *M. GULISANO[1], R. PARENTI[2], R. GULINO[2]
[1]Lab. Mol Biol / Dept Physiol Sci., [2]Dept BioMedical Sci. - Physiological Section, Univ. Catania, Catania, Italy

Abstract: Sonic hedgehog and Noggin are morphogenetic factors involved in neural induction and ventralization of the neural tube, but recent findings suggest that they could participate in regeneration and functional recovery after injury. Here, in order to verify if these mechanisms could occur in the spinal cord and involve synaptic plasticity, we measured the expression levels of Sonic hedgehog, Noggin, Choline acetyltransferase, Synapsin-I, and Glutamate receptor subunits (GluR1, GluR2, GluR4), in a motoneuron-depleted mouse spinal lesion model obtained by intramuscular injection of Cholera toxin-B saporin. The lesion caused differential expression changes of the analyzed proteins. Moreover, motor performance was found correlated with Sonic hedgehog and Noggin expression in lesioned animals. The results also suggest that Sonic hedgehog could collaborate in modulating synaptic plasticity. Together, these findings confirm that the injured mammalian spinal cord has intrinsic potential for repair and that some proteins classically involved in development, such as Sonic hedgehog and Noggin could have important roles in regeneration and functional restoration, by mechanisms including synaptic plasticity.

Title: Postsynaptic Dystrophin regulates the neurotransmitter release via a Dystrobrevin, Rho-GTPase and CaMKII-dependent pathway

Authors: *L. G. FRADKIN[1], S. POTIKANOND[2], G. S. K. PILGRAM[2], A. W. M. DE JONG[2], J. N. NOORDERMEER[2]

Abstract: Synaptic function is regulated by homeostatic mechanisms which maintain functional parameters, such as the levels of neurotransmitter release, at their wild type set points. Although significant progress has been made in identifying presynaptic homeostatic pathway members, little is known about the postsynaptic pathways involved or how the set point is maintained in

vivo. Here, we show that Dystrobrevin is delocalized from the Drosophila neuromuscular junction in the absence of Dystrophin, leading to an abnormally high set point of neurotransmitter release. Postsynaptic relocalization of Dystrobrevin in the Dystrophin mutant background restores the normal release level. Genetic epistasis experiments indicate that the pathway's chief target is the Rho-GTPase CDC42. Supporting this, postsynaptic expression of constitutively-active CDC42 alone recapitulates the Dystrobrevin mutant phenotype. Finally, we show that this pathway likely acts to regulate postsynaptic CaMKII activity. Taken together, our results outline a novel postsynaptic pathway that regulates the homeostatic neurotransmitter release set point.

Title: Glutamatergic synaptic plasticity mediates rapid escape reflex transformation during morphallactic regeneration in the annelid worm Lumbriculus variegatus.

Authors: *Z. R. LYBRAND[1], M. J. ZORAN[1], V. G. MARTINEZ-ACOSTA[2]
[1]Biol., Texas A&M Univ., College Station, TX; [2]Biol., Univ. of the Incarnate Word, San Antonio, TX

Abstract: Neural plasticity is the process by which anatomical (structural) and physiological (functional) changes in the nervous system of an organism lead to alterations in behavior. Neural morphallaxis, a rare form of neural plasticity, involves the reorganization of the animal's nervous system during segmental regeneration following injury. In Lumbriculus variegatus, an aquatic annelid worm, neural morphallaxis is characterized by synaptic changes in the neural circuits that underlie escape reflexes. Sensory-to-giant interneuron connections that mediate tail withdrawal in posterior segments transform such that sensory inputs activate head withdrawal as segments take on a more anterior position. During this transformation, neurotransmission at the sensory-to-giant interneuron synapse rapidly becomes functional suggesting that these sensory synapses are functionally silent prior to neural morphallaxis. Here we have used neurobiotin (NB), a fluorescent neural tracer dye that passes readily through gap junctions at electrical synapses, to

label the medial giant fiber (MGF) within the ventral nerve cord (VNC). A total of 9 coupled cells, including a bilateral pair of intermediate fibers, were identified. Transmission electron microscopy analysis confirmed synaptic input onto these intermediate fibers. Serial sections identified giant fiber collaterals, projections through the myelin-like sheath surrounding the MGF, with an abundance of motor output synapses, but no identifiable synaptic inputs. Intracellular current-clamp recordings of the MGF demonstrated that CNQX, an AMPA receptor antagonist, abolished all evoked MGF responses, however AP5, an NMDA receptor antagonist, showed no effect. Immunohistochemistry of the VNC showed that GluR5-7, an AMPA/kainate receptor monoclonal antibody, labeled glutamate receptors along the periaxonal regions of the MGF and the intermediate fibers. GluR5-7 was also colocalized with the monoclonal antibody Lan3-2, a molecular marker for neural morphallactic plasticity. These results suggest that the MGF pathway includes an electrically coupled network of cells. Neural morphallactic plasticity of sensory input to this coupled network is via glutamatergic synapses onto the MGF and intermediate fibers, which function as a bilateral pair of sensory interneurons. Therefore, neural morphallaxis is mediated by the rapid unsilencing of functionally effective glutamatergic synapses that are likely pervasive along the VNC.

Title: Nogo receptor signaling antagonizes growth promoting pathways to restrict synaptic plasticity

Authors: *K. T. BALDWIN, Y. A. MIRONOVA, R. J. GIGER
Cell and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Proper nervous system function critically depends on the proper assembly, maintenance, and activity-dependent modification of neuronal circuits. Although a great deal is known about extracellular molecules and signaling pathways that regulate axonal growth and pathfinding during embryonic nervous system development, comparatively little is known about the mechanisms that control synaptic structure and function in the juvenile and adult mammalian brain and spinal cord. Mounting evidence suggests that there is a close overlap of molecular

players that limit neuronal sprouting in the injured central nervous system (CNS), and molecules that restrict neuronal plasticity in the healthy (uninjured) CNS. Recent studies from our lab revealed that the growth inhibitory proteins Nogo/RTN4 and oligodendrocyte myelin glycoprotein (OMgp) suppress activity-dependent synaptic plasticity in a Nogo receptor 1 (NgR1)-dependent manner. The signaling mechanisms employed by NgR1 to regulate synaptic structure and synaptic transmission, however, have not yet been defined. Mammalian target of rapamycin complex 1 (mTORC1) promotes protein synthesis through phosphorylation of its direct substrates, p70 S6 kinase (S6K) and eIF4E-binding proteins (4EBP). BDNF elicited activation of mTORC1 is essential for protein synthesis-dependent forms of synaptic plasticity, including late-long term potentiation (L-LTP). Here we show that Nogo/NgR1 signaling negatively regulates mTORC1 activity through its interaction with signaling pathways upstream of mTORC1 activation. In primary neurons, increasing Nogo signaling causes a decrease in expression of several proteins important for activity-dependent regulation of synaptic strength, including NMDA and AMPA receptor subunits. Conversely, blocking Nogo/NgR1 signaling increases expression of these proteins, suggesting Nogo/NgR1 signaling plays a key role in regulating the composition of the synaptic proteome. Studies with Nogo receptor mutant mice indicate that signaling pathways upstream of mTORC1 are regulated by NgR1 ligands *in vivo*, and contribute to defects in synaptic transmission. Ongoing studies are exploring the role of Nogo receptors in hippocampus-dependent learning paradigms.

Title: Dynamic regulation of synaptic maturation state by voltage-gated A-type K+ channels in CA1 hippocampal pyramidal neurons

Authors: *E. KIM[1], D. HOFFMAN[2]
[1]NIH, Huntington, WV; [2]NIH, Bethesda, MD

Abstract: Neuronal activity is thought to play a critical role in the formation and modification of neural circuits during brain development while the disruption of normal neuronal activity and synaptic plasticity has been implicated in several neurological disorders. In hippocampal CA1 pyramidal dendrites, A-type voltage-gated K+ currents, formed primarily by Kv4.2 subunits,

control excitability. Here we used Kv4.2 knock-out (Kv4.2-KO) mice along with acute in vivo expression of Kv4.2 or its dominant negative pore mutant to examine the role of Kv4.2 expression in the development of CA1 synapses. We found that Kv4.2 expression induces synaptic maturation in juvenile WT mice and rescues developmentally delayed synapses in adult Kv4.2-KO mice. In addition, we show that NMDAR subunit composition can be reverted back to juvenile forms in WT adult synapses by functionally down-regulating Kv4.2 levels. We also found that abnormally abundant silent synapses in recordings from adult Kv4.2-KO mice could be remedied by Kv4.2 expression. These results suggest that Kv4.2 regulation of excitability determines synaptic synaptic maturation state.

Abstract: Hippocampal cholinergic neurostimulating peptide (HCNP) was purified as a peptide inducing the synthesis of cholineacetyltransferase in medial septal nucleus in vitro and in vivo. HCNP precursor protein (HCNP-pp) was also reported as a multifunctional protein, participating in signal pathways. We also reported that over-expression of HCNP-pp in hippocampus increased the amount of collapsin response mediator protein (CRMP)-2 with the inhibition of phosphorylation, and co-localized with total CRMP-2 at pre-synaptic terminal in hippocampus. Furthermore, it is known that CRMP-2 may dissociate from tau protein by sequential phosphorylation.
To clarify whether the phosphorylation in CRMP-2 involves in co-localization and/or the binding activity with HCNP-pp, we investigated the co-localization in immunohistochemistry and immunoprecipitation. Here, we demonstrated that HCNP-pp mainly co-localized with the non-phosphorylated CRMP-2 at pre-synaptic terminals in the hippocampus, while the phosphorylated CRMP-2 primarily presented at post-synaptic terminals. In addition, CRMP-2 by

phosphorylation may dissociate from HCNP-pp in the hippocampus. These findings suggest that HCNP-pp, in association with the non-phosphorylated CRMP-2, plays an important role in pre-synaptic function in the mature hippocampus.

Title: Non-classical targets of cAMP contribute to presynaptic plasticity in the hippocampus

Authors: *H. B. FERNANDES[1], S. KRANIOTIS[1], J. J. MARSHALL[1], S. RIORDAN[2], A. CONTRACTOR[1]
[1]Physiol., [2]Cell and Mol. Biol., Northwestern Univ., Chicago, IL

Abstract: cAMP signaling has been implicated in the mechanisms of distinct forms of long term synaptic plasticity, including those expressed in the postsynaptic spine and those expressed in the presynaptic terminal. Classically it has been thought that the actions of cAMP are through the activation of protein kinase A (PKA), resulting in phosphorylation of downstream substrates, and an increase in synaptic release of glutamate. Recently a new downstream target of cAMP has been identified which links to an alternate PKA- independent signaling pathway. This target is the cAMP guanine-nucleotide exchange factor (cAMP-GEF) Epac, which can regulate small GTPases such as Rap1. One of the members of this family, Epac2, is enriched in the brain with expression particularly high in the dentate gyrus and CA3 regions of the hippocampus. Neurotransmission at the mossy fiber synapse formed between the dentate granule neurons and the hippocampal CA3 pyramidal neurons has several characteristic features. Mossy fiber synapses display marked short-term plasticity and a robust long-term potentiation (LTP) that is expressed as a persistent increase in release probability. Elevating cAMP with forskolin induces a chemical LTP of mossy fiber synapses, which occludes further activity-induced LTP. Because of the enriched expression of Epac2 in the hippocampus we investigated whether this non-classical target of cAMP plays a role in mossy fiber plasticity. We first performed tissue

fractionation to obtain samples enriched with the large mossy fiber synaptosomes. Immunoblot analysis revealed that Epac2 was expressed at high levels in the mossy fiber boutons. To determine the functional consequence of ablation of Epac2 we performed whole-cell electrophysiological recordings from CA3 neurons in hippocampal slices obtained from Epac2 knockout ($Epac2^{-/-}$) or wild-type ($Epac2^{+/+}$) littermate mice. We found that basal synaptic transmission and short-term plasticity were not altered in $Epac2^{-/-}$ mice. Paired pulse ratios of mossy fiber EPSCs at an interstimulus interval of 40ms were 2.6 ± 0.16 (n = 20) in $Epac2^{+/+}$ recordings and 2.5 ± 0.14 (n = 23) in $Epac2^{-/-}$ recordings ($p > 0.05$). Similarly frequency facilitation at 1 Hz was not different between the two genotypes ($Epac2^{+/+}$: 2.9 ± 0.43, n = 14; $Epac2^{-/-}$: 2.5 ± 0.21, n = 16, $p > 0.05$). However, we found a significant genotype effect on tetanically induced LTP in $Epac2^{-/-}$ mice. The magnitude of LTP in $Epac2^{+/+}$ recordings 25-30 minutes after induction was 195 ± 21.5 % (n =8) whereas in interleaved recordings from $Epac2^{-/-}$ the magnitude of LTP was 133 ± 11.4 % (n =11)($p < 0.05$). These data provide evidence of a significant role for Epac2 in mossy fiber LTP.

Title: Hebbian mechanisms underlying the learning of Markov sequence probabilities

Authors: *K. BOUCHARD[1], S. GANGULI[3], M. BRAINARD[2]
[1]Neurosurg. and Physiol., [2]Physiol., UCSF, San Francisco, CA; [3]Applied Physics, Stanford, Palo Alto, CA

Abstract: The majority of natural sensory and motor events do not occur in isolation, but are embedded in the context of sequences with rich probabilistic structure. For example, the learned song of a Bengalese finch exhibits probabilistic transitions in the sequencing of song syllables. Further, we have previously shown that the conditional probability of song sequences is encoded in auditory responses of vocal control area HVC. Despite the ubiquity and generality of such learned probabilistic sequences, little is known about the mechanisms that develop synaptic weights that are proportional to the experienced statistics of probabilistic sequences.

Here, we investigate the conditions under which Hebbian synaptic plasticity shapes unstructured networks to reflect the conditional probability of sequential events.
Our basic approach is to focus on the degree to which the conditional probability of sequential events that are imposed on a network through training stimuli become encoded in the synaptic weights of recurrent neural networks of rate based units. For simplicity, we equate each node in our network with an elemental behavioral action and ask whether Hebbian plasticity can learn to connect nodes of the network with synaptic weights that reflect the transition probabilities between the corresponding actions.
We show through analytics and simulations that Hebbian synaptic plasticity with pre-synaptic competition develops synaptic weights proportional to the conditional forward transition probabilities [P(s(t+1)|s(t))] present in the input sequence. In contrast, post-synaptic competition develops synaptic weights proportional to the conditional backward probabilities [P(s(t-1)|s(t))] of the same input sequence. We demonstrate that to stably but flexibly reflect the conditional probability of a neuron's inputs and outputs, local Hebbian plasticity should approximately balance the magnitude of synaptic depression relative to potentiation (a competitive force) with the weight dependence of synaptic change (a homogenizing force). These forces interact to control both the rate at which structure emerges and the entropy of the final distribution of synaptic weights. Thus the relative balance of these forces induces a prior over learnable transition distributions. Together, these results demonstrate a remarkably simple correspondence between biophysics and probabilistic sequence learning: the site of synaptic competition dictates the temporal flow of the learned probabilistic structure and the balance between competitive and homogenizing forces dictates a prior expectation of the randomness of the sequence to be learned.

Title: Muscarinic control of presynaptic long-term potentiation at parallel fiber-Purkinje cell synapses

Authors: L. RINALDO[1], *C. HANSEL[2]
[1]Univ. of Chicago, Chicago, IL; [2]Neurobio., Univ. Chicago, CHICAGO, IL

Abstract: The activation of muscarinic acetylcholine receptors is known to modulate synaptic plasticity by promoting the production and release of cannabinoids in certain brain areas. In the cerebellar cortex it has been shown that cannabinoid signaling can block the induction of presynaptic long-term potentiation (PF-LTP) at parallel fiber-Purkinje cell (PF-PC) synapses. Herein, we demonstrate that the muscarinic agonist oxotremorine-m (oxo-m; 7 μM) blocks the induction of PF-LTP in a cannabinoid-dependent manner when applied during the tetanization period. Under control conditions, 120 parallel fiber stimuli delivered at 8 Hz resulted in LTP of parallel fiber EPSC's (123.9 ± 8.8%; n = 12; t = 31-35 min after; p0.05). PF-LTP was restored when the cannabinoid receptor antagonist AM251 (3 μM) was present in the bath with oxo-m (117.6 ± 5.6%; n = 7; p<0.05), indicating that muscarinic receptor activation triggers cannabinoid release in the cerebellar cortex. There are five known isoforms of muscarinic acetylcholine receptors (M1-5), of which M1, M3, and M5 are G_q-coupled receptors that exert their actions through phospholipase C (PLC), a key element in the enzymatic pathway responsible for cannabinoid production. As the effect of oxo-m on PF-LTP was abrogated by the PLC inhibitor U-73122 (122.6 ± 6.6%; n = 7; p<0.05), it is likely that one of these receptor subtypes is mediating this effect. Finally, oxo-m did not block the induction of PF-LTP when the guanosine nucleotide analogue GDP-β-S was added to the recording pipette (133.5 ± 7.9%; n = 7; p<0.05), indicating that cannabinoid production results from activating muscarinic receptors located on Purkinje cells. To compare the effects of muscarinic activation on plasticity expressed post-synaptically versus pre-synaptically, we applied oxo-m during the tetanization protocol for a post-synaptically expressed form of LTP. We found that in some cases the agonist converted the LTP to an LTD (Control: 113.1 ± 4.3%; n = 4; p<0.05; Oxo-m: 91.1 ± 8.2%; n = 6; p>0.05). Preliminary data suggests that this effect may be PKC-dependent, as it was somewhat reversed when the PKC inhibitor chelerythine (10 μM) was present in the bath throughout the recording (98.1 ± 8.3%; n = 4; p = 0.82). These results suggest that muscarinic receptors in the cerebellar cortex can control both pre- and postsynaptically expressed forms of plasticity, possibly through PLC-dependent pathways.

Title: Evidence for the activation of presynaptically silent cortical synapses using a fluorescent probe

Authors: *T. HIKIMA, G. ARBUTHNOTT
Brain Mechanisms for Behaviour Unit, Okinawa Inst. of Sci. and Technol. Grad. Univ., Onna-Son, Okinawa, Japan

Abstract: There are several modes of changing synaptic strength and one of them is activating silent synapses. Activation of silent synapses is thought to provide reserve capacity for new neuron network processing or storage. There is ample evidence for postsynaptically silent synapses with only NMDA receptors present (e.g., Ashby & Issac, 2011 Neuron70, 510-521) but the variation of presynaptic release probability has been much less studied. We focused on adenlyl cyclase (AC) and protein kinase A (PKA) enhancement of synaptic release. We have used a method to measure exocytosis directly at presynaptic terminals in which a fluorescent pH reporter (Synaptophysin-pHluorin 2x, SypH2x) is transfected into neurons to allow us to image synaptic vesicle release. We applied this optical method to terminals of cortical neurons and measured the SypHx2 fluorescence from individual presynaptic terminals in response to electrical stimulation. Forskolin (FSK) was used as the AC/PKA activator and the SypH2x fluorescence response to stimulation was compared before and after FSK treatment. Stimulation with 5 pulses at 20Hz resulted in an increase of fluorescence on average across many terminals. The FSK treatment (10µM) enhanced the peak SypH2x fluorescence amplitude significantly. Considering synapses change their strength by jumping between discrete states, we define an active terminal as one whose fluorescence became more than twice the noise after stimulation, and a silent synapse, as one whose fluorescence remained less than twice the noise after stimulation. In this way we counted the number of terminals actively releasing transmitter. FSK treatment increased the number of such active terminals. After pretreatment of kt5720 (200nM), PKA antagonist, FSK treatment had no effect. Our result suggests that AC/PKA activation enhances the number of actively releasing cortical presynaptic terminals which is likely to increase overall synaptic efficacy.
We are grateful for the gift of SypH 2x from Dr Yongling Zhu

Title: Synaptotagmin-12 is a PKA target required for presynaptic mossy fiber LTP

Authors: *T. J. YOUNTS[1], Y. J. KAESER-WOO[2], T. C. SUDHOF[3], P. E. CASTILLO[1]
[1]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., BRONX, NY; [2]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [3]Howard Hughes Med. Inst. and Dept of Mol. and Cell. Physiol., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Synaptotagmins (Syts) are membrane bound proteins, some of which are essential for neurotransmitter exocytosis. Sixteen isoforms of Syts have been identified. While key physiological roles have been ascribed to Ca2+-binding Syts1, 2, 7, 9 and 10, very little is known about other Syts that do not bind Ca2+, including Syt12. Syt12 is expressed in many brain regions, like the hippocampus, and is localized to synaptic vesicles. In addition, Syt12 can be phosphorylated in a cAMP-dependent manner at serine 97 (S97) in vitro, suggesting Syt12 could be modulated by PKA signaling in vivo. PKA can modulate transmitter release and is required for many forms of presynaptically expressed long-term synaptic plasticity, which are thought to be important for learning and memory. To determine the contribution of endogenous Syt12 to synaptic transmission and plasticity as well as a possible role for S97 in PKA-dependent signaling, we generated Syt12 knock-out and S97A knock-in mice. Synaptic transmission and plasticity were investigated using hippocampal slice electrophysiology. Results indicate that Syt12 and S97 of Syt12 are not required for basal excitatory and inhibitory synaptic transmission or short-term plasticity, as well as endocannabinoid-mediated long-term depression of inhibition. However, classical presynaptic mossy-fiber LTP and pharmacological potentiation of the cAMP/PKA-pathway at this synapse were significantly compromised in Syt12 knock-out and S97A knock-in mice. Taken together, these results identify a single amino acid in Syt12 as a PKA target required for long-term modulation of neurotransmitter release at a specific hippocampal synapse. Moreover, we reveal for the first time an endogenous role for Syt12 protein in brain.

Title: Over-expression of hippocampal cholinergic neurostimulating peptide precursor protein enhances hippocampal synaptic plasticity

Authors: D. KATO, M. MIZUNO, T. KANAMORI, T. TOYODA, K. OJIKA, *N. MATSUKAWA
Nagoya City Univ., Nagoya, Japan

Abstract: Hippocampal cholinergic neurostimulating peptide (HCNP) induces the synthesis of acetylcholine in medial septal nucleus *in vitro* and *in vivo*. HCNP precursor protein (HCNP-pp) is a multifunctional protein that participates in a number of signaling pathways, including Mitogen-activated Protein Kinase (MAPK)/extracellular signal and G-protein-coupled receptor kinase 2.
We recently demonstrated that the amount of collapsin response mediator protein-2 (CRMP-2) is increased in the hippocampus of HCNP-pp transgenic mice (Tg) and that HCNP-pp, in association with CRMP-2, might plays an important role in presynaptic function in the hippocampus by regulating synaptophysin expression.
To clarify the function of HCNP-pp in the neural activity and its effects on synaptic plasticity, we examined basal synaptic transmission and long-term potentiation (LTP).
Here, we demonstrate that basal synaptic transmission is slightly increased and LTP induction is greatly facilitated in HCNP-pp Tg mice as compared to wild-type littermates.
These findings suggest that HCNP-pp affects synaptic efficacy in the hippocampus.

Title: Investigating the role of glutamate receptors in hippocampal, mossy fibre LTP *in vivo*

Authors: *J. WALLIS, D. E. JANE, G. L. COLLINGRIDGE, Z. A. BORTOLOTTO
Univ. of Bristol, Bristol, United Kingdom

Abstract: Glutamate is the primary excitatory neurotransmitter in the mammalian central nervous system, with glutamate receptors well documented for their roles in multiple forms of synaptic plasticity. NMDA receptors are integral for the induction of numerous, classical forms of long-term potentiation (LTP) and long-term depression. The hippocampal mossy fibres demonstrate an unsual form of NMDA receptor independent LTP. Both kainate receptors (KARs) and metabotrobic glutamate (mGlu) receptors have been implicated in this MF-LTP but their roles remain controversial. Recently our group has shown that antagonism of either GluK1-containing kainate receptors (with ACET or LY383885) or group I mGlu receptors (using a combination of 2-Methyl-6-(phenylethynyl) pyridine hydrochloride (MPEP) and LY367385) can inhibit MF-LTP (Dargan et al, 2009; Nistico et al., 2011). However, the sensitivity of MF-LTP to GluK1 antagonists is highly dependent on such factors as the divalent cation concentration (Lauri et al, 2003) and the slice orientation (Sherwood et al, 2012). As a result of the variability associated with in vitro approaches we sought to assess the roles of these receptors under more defined physiological conditions, by investigating the effects of GluK1 and mGlu receptor antagonists in vivo.

We studied the roles of KARs and mGlu receptors in the induction of MF-LTP, in anaesthetised rats. MF field EPSPs were evoked by stimulation of the granule cells, in dentate gyrus and were recorded in stratum lucidum of the CA3 region of the hippocampus. Drug application was made via an intrahippocampal cannula attached to the recording electrode. Ketamine (10mg/kg I.V.) was applied 10 minutes prior to tetanisation. LTP was induced by two tetani (2 x 100 Hz, 1 s). (2S,2'R,3'R)-2-(2',3'-Dicarboxycyclopropyl) glycine (DCG-IV) (2µl of 10µM I.H.) was applied after a 90 min and induced substantial depression of evoked synaptic transmission.

The present findings showed that a range of UoB synthesised, GluK1 targeting antagonists did not block the induction of MF-LTP. Furthermore mGlu receptor antagonism with (RS)-α-Methyl-4-carboxyphenylglycine (MCPG) demonstrated only limited affect on MF-LTP induction. However, co-application of MCPG and KAR antagonists at multiple concentrations significantly impaired MF-LTP. Further investigation into the mGlu receptor subtypes responsible, suggested that the effects are likely mediated via group I mGlu receptors.

These data suggest that both group I mGluRs and KARs are stimulated during, but the activation of only one type is required for, the induction of MF-LTP in vivo.

Title: Neuronal homeostasis: Inside the black box.

Authors: *T. O'LEARY, E. MARDER
Volen Ctr. For Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Individual neurons develop characteristic electrical properties that remain stable over the lifetime of an organism despite various physiological perturbations including ion channel turnover, changes in morphology and variation in afferent input [1]. The electrical properties of neurons are controlled by cellular processes that govern ion channel regulation and these processes are thought to be activity-dependent and homeostatic in nature. Although a considerable amount of experimental evidence supports the existence and characterizes the properties of such homeostatic regulation, the details of the underlying mechanisms are unknown [2,3]. As a result, numerous conceptual models appear to be compatible with existing experimental data when implemented in simulations [4], but it is not presently clear how these models relate to one another, nor whether they constrain possible behaviour in a manner that permits experimental falsification [5]. For example, certain models (proportional controllers) predict incomplete compensation, whilst others (integral controllers) may exhibit undershoot and overshoot, or 'ringing'. We examine the abstract form of several existing models of activity-dependent ion channel regulation and show how each makes distinct, testable predictions that have not been fully investigated in an experimental setting. We relate these abstract controller models to the generic biochemical processes they correspond to in a living cell, such as ion channel insertion and calcium-dependent gene expression. Finally, we assess the sensitivity of the models to random fluctuations that are present in all biochemical systems and find that this sensitivity places constraints on the controller type. Together, our results may help eliminate candidate models of homeostatic regulation therefore constrain the form of the biological signalling pathways that the models describe.

Title: Differences in intrinsic properties between dorsal and ventral CA1 pyramidal neurons

Authors: *M. MAROSI, C. HÖNIGSPERGER, J. F. STORM
Dept. of Physiol., Univ. of Oslo, Oslo, Norway

Abstract: The hippocampus shows differences in neuronal connectivity and molecular markers along the dorso-ventral axis. Behavioral and other studies indicate that the dorsal part of the hippocampus performs mainly cognitive functions, whereas the ventral is involved in emotions and stress, and place fields are larger for ventral CA1 cells. In this study we examine whether there are differences in the intrinsic electrophysiological properties of dorsal and ventral CA1 pyramidal neurons. Using somatic whole-cell patch-clamp recordings from CA1 pyramidal neurons (n=78), we tested their ability to generate subthreshold membrane potential oscillations (MPO), to respond selectively to oscillating current injections at different frequencies (resonance), and to integrate postsynaptic potentials. We also compared resting membrane potential, input resistance, spike afterpotentials, and repetitive firing evoked by depolarizing current steps. To study resonance at subthreshold potentials, we applied a frequency-modulated sinusoidal current whose frequency increased linearly with time. Our results shows that the majority of dorsal CA1 pyramidal neurons (n=22/30) have a prominent resonance peak (frequency: 2.5±0.3Hz) compared to the ventral side where only few cells (n=7/30) showed detectable resonance, and the resonance frequency was lower (0.8±0.2Hz). We also observed a significant difference in frequency of subthreshold MPOs and in the synaptic potential integration at depolarized potential. MPOs in CA1 pyramidal neurons are probably generated by interplay between persistent Na^+ current and a slowly activating K^+ current, and it has been shown that subthreshold theta resonance in these cells is generated by Kv7/M-type K^+ channels and persistent Na^+ current. The Kv7 channels also regulate excitability, spike afterpotentials, and spike frequency adaptation. We tested the effects of the selective Kv7 channel blocker XE991, as well as muscarine, which also inhibits Kv7/M channels. Application of XE991 and muscarine lowered the spike threshold and eliminated MPOs and the theta resonance, and thus had stronger effects in dorsal CA1 pyramidal cells where these Kv7/M-channel-dependent features were most prominent. XE991 also increased the synaptic integration in the dorsal CA1 pyramidal cells. Our

findings indicate that the biophysical properties of CA1 pyramidal cells differ along the dorso-ventral axis, involving Kv7-dependent mechanisms, including theta resonance, subthreshold synaptic integration and membrane potential oscillations. These dorso-ventral differences may be related to cognitive/spatial vs. emotion-related functions.

Title: Spike phase locking in CA1 pyramidal neurons depends on background conductance and firing rate

Authors: *T. BROICHER[1], P. MALERBA[2], A. D. DORVAL[2], A. BORISYUK[3], F. R. FERNANDEZ[2], J. A. WHITE[2]

Abstract: Oscillatory activity in neuronal networks correlates with different behavioral states throughout the nervous system, and the frequency-response characteristics of individual neurons are believed to be critical for network oscillations.
Recent in vivo studies suggest that neurons experience periods of high membrane conductance, and that action potentials are often driven by membrane-potential fluctuations in the living animal.
To investigate the frequency-response characteristics of CA1 pyramidal neurons in the presence of high conductance and voltage fluctuations, we performed dynamic-clamp experiments in rat hippocampal brain slices.
We stimulated neurons with Poisson-process-driven inputs with sinusoidal modulation, and determined action potential phase-locking profiles with respect to background conductance and firing rate.
Modulations covered a wide range of physiological frequencies, encompassing the delta, theta, beta, and gamma bands.

We found that background conductance and firing rate qualitatively change the phase locking of CA1 pyramidal neurons: across conditions, we observed low-pass and band-pass profiles, the latter centered at either theta or beta-gamma ranges.
Three factors are important in shaping phase-locking profiles in response to changes in firing rate or membrane conductance.
Phase locking to low modulation frequencies is dominated by the degree of spike-rate adaptation.
Intrinsic frequency preferences in the spike-generating mechanism contribute to mid-frequency phase locking.
Responses to high modulation frequencies are dominated by the action potential cutoff frequency of the postsynaptic membrane.
Together, these mechanisms may provide pyramidal cells with the ability to adjust their frequency preference in response to the global changes in activity associated with different behavioral states.

Title: Novel molecular players of homeostatic intrinsic plasticity

Authors: *K. LEE, S. ROYSTON, M. VEST, D. LEY, H. CHUNG
Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Homeostatic plasticity of intrinsic excitability (Intrinsic plasticity) encompass the regulatory mechanisms by which neurons maintain a physiologic balance between neuronal excitation and inhibition, and is thought to play a large role in the pathogenesis of epilepsy and pain disorders. However, the molecular basis of this important plasticity is unknown. Here we show that prolonged blacked of neuronal activity by tetrodotoxin (TTX, voltage-gated sodium channel antagonist) leads to a compensatory increase in intrinsic excitability in dissociated hippocampal cultures neurons. Conversely, prolonged enhancement of neuronal activity via

bicuculline (BC, GABAA receptor antagonist) administration results in a homeostatic decrease in intrinsic excitability. To identify novel gene transcripts whose expression is mediated by global activity changes, we performed cDNA microarray analysis following induction of homeostatic intrinsic plasticity. Genes involved "K^+ ion transport" were significantly overrepresented, the majority of which encodes K^+ ion channels that critically function to dampen neuronal excitability. TTX treatment repressed 11 out of 12 K^+ channel genes, whereas BC treatment induced 4 out of 7 K^+ channel genes. In particular, a significant bidirectional change was found for genes responsible for A-type potassium currents that serve as a critical brake for repetitive firing of action potentials. We have verified activity-dependent changes in K^+ channel gene expression using quantitative real-time PCR. Furthermore, the observed TTX and BC-induced changes in excitability correlate with induce changes in the protein expression and current density of these K^+ channels. Most importantly, the observed TTX-induced homeostatic increase in excitability is mimicked by inhibition of NMDA receptors but not L-type voltage gated calcium channels. Together, our findings suggest that activity-dependent expression of K^+ channels and their associated proteins via NMDA receptor-dependent signaling may contribute to the stabilization of hippocampal neuronal excitability by serving as key proteins in the molecular mechanisms governing homeostatic intrinsic plasticity.

Title: Adaptation induced by slow inactivation of Na channels underlies depolarization block in a model dopamine neuron

Authors: *K. QIAN[1,2], M. A. HUERTAS[1], C. C. CANAVIER[1]
[1]Cell Biol. and Anat., [2]Neurosci., LSUHSC, New Orleans, LA

Abstract: Dopamine neurons pace spontaneously in vitro but go into depolarization block (DB) at applied current levels that are not sufficient to elicit the high frequency firing observed during behaviourally relevant bursts in vivo. Thus simple depolarization is not sufficient for burst signaling in vivo. Also, induction of DB in dopamine neurons has been correlated with the

efficacy of antipsychotic drugs, and antipsychotics have been shown to rapidly induce depolarization block in a developmental rat model of schizophrenia. When entering DB during an applied current step, full amplitude spikes are produced until spike failure occurs at potentials near the original spike threshold.
In order to capture the essential features of depolarization block, we started with a one compartment model of a dopamine neuron with a sodium current rigorously fitted to recent published experimental data, and a single composite potassium current. A fast-slow analysis was used to reduce the model to two variables, and as the stimulus current was increased the model entered DB in manner inconsistent with experimental observations. The maximum hyperpolarization after an action potential decreased and the membrane potential hung up at a depolarized potential relative to the initial spike threshold. Adding a second component of sodium channel inactivation that inactivates sharply above -50 mV but recovers slowly at hyperpolarized potentials allowed the model to enter DB in a manner consistent with experimental observations. Bifurcation analyses showed that the mechanism underlying the two types of transition into depolarization block are distinct. Preliminary results indicate that a slow activation of a potassium current cannot be responsible for a transition from pacemaking to DB consistent with experimental observations. Some of these results have been reproduced in a morphologically realistic, multicompartmental model of a dopamine neuron. Preliminary modeling results show that activation of an NMDA conductance can delay the entry into depolarization block, consistent with a role for that current in circumventing the frequency limitation during bursts in vivo.

Title: A model of carbachol dependent, self-terminating persistent activity in the rat somatosensory cortex

Authors: *S. ZIBMAN[1], H. SOMPOLINSKY[2,3], Y. YAROM[2]
[2]ELSC, [1]Hebrew Univ., Jerusalem, Israel; [3]Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: Muscarinic activity has long been known to play a role in the functions of the somatosensory cortex (Sarter and Bruno, 1997). Additional studies have shown somatosensory neurons to display persistent activity during behavioral tasks (Fuster, 2004). Together these findings make the somatosensory cortex an attractive candidate to find single neuron muscarinic dependent persistent activity.

Using whole cell recordings accompanied by pharmacological agents, we explored persistent activity in the rat somatosensory cortex. In the presence of 20 μM carbachol, a one second burst of action potentials at 30Hz was followed by a slow after-depolarizing potential (ADP) often associated with seconds long burst of spikes. The distribution of spiking duration is multimodal with a maximum duration surpassing one minute. Using a hybrid clamp protocol, we measured a peak inward current of 15pA occurring at -60 mV with a decay of 4 seconds. The addition of 50 μM flufenamic acid (FFA), a specific blocker of calcium dependent nonspecific cation current (I_{CAN}), prevents the appearance of persistent activity, thus indicating the involvement of I_{CAN}. The fact that spiking exceeds the length of non-spiking ADPs indicates that the spiking is a regenerative process and not merely the result of the I_{CAN} raising the voltage above threshold. Yet, suppressing the spiking response for up to 30 seconds using hyperpolarizing pulses did not prevent a subsequent renewal of the spiking response. This indicates that there is also a component which is not dependent on the spiking. Based on the observation that emptying internal calcium stores with 2 μM thapsigargin reduces the inward current, we suggest that this component relates to the inositol 1,4,5-triphosphate (IP_3)-induced Ca^{2+} release from internal stores.

We present here a model that successfully reproduces these experimental findings. Persistent activity results from balancing two calcium sensitive currents, I_{CAN} and a potassium current with spike induced calcium influx. Calcium is also released from internal stores and is maintained by calcium's up regulation of IP_3 production during the early part of the response, thus providing a temporary independence of the calcium levels from the spiking. Once internal calcium release returns to base levels, persistent activity becomes sensitive to the firing rate of the neuron. Intrinsic noise can disrupt the firing rate and by extension the influx of calcium. We show that the presence of this noise explains the multimodal distribution of the spiking duration.

Res., Basel, Switzerland; [6]Pázmány, Budapest, Hungary

Abstract: The understanding of brain computations requires methods that read out neural activity on different spatial and temporal scales. Although following signal propagation and integration across a neuron and recording the concerted activity of hundreds of neurons pose distinct challenges, a single recording system performing both operations is desirable. Here we present a three-dimensional (3D), high-resolution, acousto-optic two-photon microscope with continuous 3D trajectory and random-access scanning modes reaching a millimeter scan range (up to 1,000 x 1,000 x 2,000 μm^3 in transparent sample), adaptable to different spatial scales. The subcellular scale is demonstrated by presenting 3D optical recordings of action potential back propagation in hundred locations and dendritic Ca^{2+} spike forward propagation in long dendritic segments situating in *in vitro*, at near-microsecond temporal resolution. Here, the high temporal resolution of mean transients made overcoming Nyquist's sampling theory possible by using a method adopted from oscilloscope technology. Finally, the network scale is shown by volumetric random-access Ca^{2+} imaging of spontaneous and visual stimulation-evoked activity from hundreds of neurons in the visual cortex *in vivo*.

Title: The impact of early life stress on *in vitro* gamma oscillations

Authors: *K. NEWLING, G. RENTESI, M. KAISER, M. O. CUNNINGHAM
Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Early life adversity in the form of abuse, neglect or parental loss during early development is associated with an increased risk of many neuropsychological disorders in adulthood. These include depression, post-traumatic-stress disorder, panic disorder, attention deficit disorder (for review see 1) as well as psychosis [2] and schizophrenia [3]. Stress exposure in early life is also linked to deficits in cognitive function, including impaired spatial learning and memory [4].

A well-established rodent model of early life stress is 24 hour maternal deprivation at postnatal day 9[5]. Maternally deprived (MD) adults display a range of behavioural impairments, many of which are commonly described in neuropsychiatric disease [6]. MD rodents show alterations in the stress response system, hippocampal morphology and specific NMDA receptor expression. However, little information exists concerning the impact of early life stress on neuronal function, including the ability of cortical networks to generate persistent rhythmic activity of cognitive relevance.

Gamma oscillations (30-80Hz) are crucial for the coordination of neural activity across many brain areas simultaneously [7] and are involved in many cognitive functions [8, 9]. We examined these oscillations in MD adult male Wistar and control rats, which remained with the dam until weaning at postnatal day 21.

Extracellular local field potential (LFP) recordings were taken in LII/III of the medial entorhinal cortex (mEC), and the CA3 subfield of the hippocampus (HPC), in combined EC-hippocampal brain slices (450µm) prepared from MD and control adult rats. Gamma oscillations were induced by bath application of kainate (2-500nM). Results will potentially reveal a difference in gamma frequency and power between MD and control groups, and we hypothesize that disruptions of cortical interneuronal function underlie any deficiencies. Pharmacology and post-hoc immunocytochemistry will be used to examine any differences in parvalbumin positive interneuron number and connectivity.

Title: Mixed lattice models of charge distribution, interactions and transport in neural tissue

Authors: *S. PAJEVIC
MSCL/CIT/DCB, NIH, BETHESDA, MD

Abstract: In equilibrium, the intracellular space is at a negative potential relative to the extracellular space as a result of active transport of ions across the lipid bilayer membrane and the balance of concentration and electrical gradients. In the first part we study the charge distribution at the membrane interface and within tight extracellular spaces, in the simplest form described by the diffuse electrical double layer model. Here we extend this model to planar interfaces containing an ordered lattice of cylindrical channels, representing the transmembrane protein channels often organized into a long-range lattice order. As a particular example we use hexagonal lattice of gap junctions, and study the closed and open state (without or with current) configurations. The lattice constant (~80 A) and the radii of the approximating cylinders (~20 A) are comparable to the Debye or Bjerrum lengths, hence the structure of the lattice will be reflected in the distribution of the charges. This equilibrium model of charge distribution applies also to the non-excitable tissues, such as liver or pancreas. In the second part we focus on the excitable tissues, in our particular case the neural tissue abundant in gap junctions, and propose a non-equilibrium dynamical model. The model focuses on oscillations and transitions in non-diffusive transport and conductivity, to be contrasted with the intracellular diffusive transport that is usually emphasized in the case of gap junctions. Structurally the model contains a mixed hierarchy of lattices, suggesting that the lattices can possess different symmetries at different levels of the hierarchy (or that at particular level the lattice itself is mixed), but also that the interactions and the dynamics of collective modes at different levels can potentially be treated in a mixed fashion, the ones at higher levels treated classically. In the case of gap junctions we presently exclude the symmetries at finer scales, for example the hexagonal arrangements of connexins in a connexon, or helical or other symmetries of atoms within connexin, and focus only on two levels. The first is a honeycomb lattice of ionic traps that approximates the above derived distribution, and the second is a quasi-periodic lattice of potential wells, an idealization of the interdigitated character of the extracellular and intracellular domains which can be extended to planar or volumetric forms. In neural tissue, consisting of neurons and glial cells, this "brain lattice" model provides an interaction dependent relationship between the spatio-temporal pattern of neuronal activations and the pattern of collective modes, as the system’s relevant degrees of freedom.

Title: Differentation with primo vessel and smooth muscle in action potential

Authors: *Y. RYU, S. CHO, S. LEE, S. LEE, K. CHOI, S. YEON, S. CHOI
Dept Acupuncture, Meridian & Moxibustion, Korea Inst. Oriental Med., Daejeon, Korea, Republic of

Abstract: Recently, certain researchers have become interested in Primo-vascular system (the scientific name for Bonghan system) and have tried to investigate Primo-vascular system by finding Primo-node (Bonghan corpuscle) and Primo-vessels (Bonghan ducts) . It was too difficult to study the functions of Primo-vessels directly because of their small size. Therefore, more research based on electrophysiology was needed, for example, action potential measurements. It is well known that tissues have different action potentials depending on their structure and function. Thus, We studied the action potential of Primo-vessels in rats to determine the electrophysiological characteristics of these structures
The study presented herein was a comparison of the action potentials generated by Primo-vessels with the pacemaker potential, made by smooth muscle from the small intestine. We also introduced a mathematical analysis method, a normalized Fourier transform that is more useful for viewing the waveform and phase than the power spectrum from a general Fourier transform. We introduced a mathematical analysis method, a normalized Fourier transform that displays the sine and cosine components separately, to compare the action potentials of Primo-vessels with those for the smooth muscle. We found that Primo-vessels generated two types of action potential pulses that differed from those of smooth muscle: 1) Type I pulse had rapid depolarizing and repolarizing phases, and 2) Type II pulse had a rapid depolarizing phase and a gradually slowing repolarizing phase.
The sharp top and larger amplitude of the pulses generated by the Primo-vessels could distinguish them from the pulses generated by the smooth muscle; thus, it is possible to assume that the Primo-vessels perform a different function from the smooth muscle. For confirmation of this hypothesis, further study is needed regarding the physiological mechanism responsible for generate these pulses and regarding which ion channels are used.

Abstract: Müller cells constitute the main glial cell type in the retina and span the tissue from the inner to the outer limiting membranes. Several functions have been attributed to these cells including structural and nutritional roles as well removal of ions and neurotransmitters from the extracellular space. The potential of Müller cells to actively participate in cellular communication within the nervous system has been recently uncovered. Moreover, it has been suggested that this type of cell can undergo de-differentiation process upon specific signals and become a progenitor-like cell. Also, it has been shown that Müller cells can generate neurons under appropriate conditions. The knowledge on controlling this particular differentiation could be extremely useful as potential therapy against neurodegenerative disorders. In the present work, we evaluate the capability of Müller cells to be used as a source of neuronal cells and evaluate the functional dopaminergic differentiation of Müller glia into dopamine releasing cells. We have shown that Müller cells in culture (n=3) not only express dopaminergic markers as the dopamine transporter (DAT), tyrosine hydroxylase (TH), dopa decarboxylase (DDC) and the transcription factor for dopaminergic differentiation Nurr1 but they are also able to produce and release dopamine in vitro (n=5), reaching values of 50 ± 10nmoles or 65 ± 8nmoles, when treated either with 10µM forskolin (FK) or 10nM PACAP38, respectively. TH activity assay confirms increase in TH activity in these cells after treatment with FK or PACAP38. Moreover, injection of functional dopaminergic differentiated Müller cells in mouse model of Parkinson's disease obtained with stereotactic injection of 6-OH-DA in the striatum clearly reduced the typical apomorphine-induced rotational behavior presented by the animals (n=7).

Title: Behavioral and inflammatory responses to photothrombotic lesions in mice deficient for astrocyte intermediate filaments

Authors: *M. J. PORRITT, Y. DEPABLO, U. WILHELMSSON, M. NILSSON, M. PEKNA, M. PEKNY
Univ. of Gothenburg, Inst. for Neurosci. and Physiol., Gothenburg, Sweden

Abstract: Astrocytes are important for normal CNS maintenance and homeostasis. After brain ischemia, astrocytes become reactive and limit further tissue loss. Hallmarks of reactive gliosis are cellular hypertrophy of astrocyte processes and the upregulation of astrocyte intermediate filament proteins glial fibrillary acidic protein (GFAP) and vimentin. Reactive astrocytes also change the expression of many other genes. We previously demonstrated that following focal brain ischemia, the infarct is increased in mice deficient in both GFAP and vimentin (*GFAP*$^{-/-}$ *Vim*$^{-/-}$), but not in *GFAP*$^{-/-}$ or *Vim*$^{-/-}$ mice, and proposed that astrocyte intermediate filaments are important for neuroprotection in ischemic stroke. Here we studied the role of astrocyte intermediate filaments in the brain tissue response and behavioral recovery after focal cortical photothrombotic lesions. Ischemic lesion volumes between *GFAP*$^{-/-}$*Vim*$^{-/-}$ and wild-type (WT)

mice did not differ at 1 or 3 days post ischemia. Gender did not affect lesion volume. The number of neutrophils within the infarct 3 days after ischemia was higher in *GFAP*$^{-/-}$*Vim*$^{-/-}$ males mice than in WT males (p<0.018) and this difference was more pronounced within the infarct core (p<0.008) than the peri-infarct area. *GFAP*$^{-/-}$*Vim*$^{-/-}$ males showed lower number of microglia both in the peri-infarct and infarct core compared to WT males (p<0.045 and p<0.022, respectively). Proteomics analysis of the infarcted cortex 1, 2 and 3 days after ischemia suggests that components of the inflammatory system are upregulated in *GFAP*$^{-/-}$*Vim*$^{-/-}$ mice. ELISA quantification of the third complement component (C3) in the infarcted cortex showed that 1 day after ischemia, *GFAP*$^{-/-}$*Vim*$^{-/-}$ mice had substantially higher levels of C3 protein than WT mice (p<0.05). One day after ischemia, the neurological deficit was larger in *GFAP*$^{-/-}$*Vim*$^{-/-}$ than WT mice. Remarkably, 3 days after ischemia *GFAP*$^{-/-}$*Vim*$^{-/-}$ mice showed the same motor function as WT mice. We show that mice deficient in intermediate filament proteins GFAP and vimentin have reduced capacity to limit the lesion-induced loss of function in the very acute phase after ischemia, possibly due to altered modulation of the inflammatory response, but they reach remarkable functional recovery shortly thereafter.

Title: Using *Drosophila* to model fluid volume regulation of the nervous system

Authors: W. M. LEISERSON, N. GONG, *H. S. KESHISHIAN
MCDB Dept., Yale Univ., New Haven, CT

Abstract: The nervous systems of humans and many animals are isolated from the rest of the organism by blood-brain and blood-nerve barriers. Membrane proteins, including pumps, transporters, and channels, permit the tight regulation of the extracellular ionic environment. The nervous system is, as a consequence, sensitive to osmotic differences between it and the rest of the organism, and the ability to regulate both ion composition and fluid volume likely co-evolved with the barrier. In humans, loss of fluid regulation, such as occurs following stroke or TBI, can have severe clinical consequences. We have identified two components of a molecular system in

Drosophila, conserved in humans, that regulates extracellular volume in the nervous system: the Na-K-Cl cotransporter, Ncc69, an ortholog of human NKCC1; and the kinase, Fray, an ortholog of human SPAK. Ncc69 and Fray function in the barrier glial cells of larval nerves. Knockdown mutations in either of the genes cause a neuropathy, where fluid accumulates within the nerves, resulting in dramatically increased nerve diameters. Mutations in either gene can be rescued by its corresponding mammalian ortholog, demonstrating a conserved molecular mechanism. Like Ncc69, human NKCC1 is found in barrier cells of the nervous system, and has been implicated in volume regulation. To find other molecular components that function to regulate the volume of the nervous system, we have undertaken a candidate RNAi screen, knocking down gene expression in the barrier glial cells, looking for swollen nerves. We identified Wnk, whose mammalian homologs regulate volume by influencing SPAK and NKCC1. Increased nerve widths were also observed when knocking down either of two K2P (two-pore-domain potassium channel) genes or the gene encoding the alpha subunit of the Na/K ATPase. Mutants bearing Wnk alleles have a nerve phenotype resembling that of fray and Ncc69, with nerve bulges that are nearly 10 times the width of normal nerves. TEM of the RNAi knockdown of Task6, one of the K2Ps, revealed fluid accumulation in the nerves, similar to Ncc69 and fray. In addition, the barrier glia in Task6 knockdowns had an unusual number of membrane foldings, in which the septate junctions appeared disorganized. Our results show that aspects of the molecular mechanisms that regulate the fluid volume of the nervous system are highly conserved. The Drosophila molecular and genetic toolkit provides a means, therefore, to gain further insights into fluid regulation in vivo, revealing mechanisms that are relevant to fluid regulation in the human nervous system.

Title: IKKβ inhibits adult neurogenesis in the hippocampal dentate gyrus in mice

Authors: K. SEONG[1], M. BAEK[1], S. CHOI[1], J. JUNG[1], W. KIM[1], *M. KIM[2]
[1]Med. Resarch Ctr. for Biomineralization Disorders, Dept. of Oral Physiology, Sch. of Dentistry, Univ. of Chonnam Natl., Gwangju, Korea, Republic of; [2]Biologic and Materials Sci., Sch. of Dentistry, Univ. of Michigan, Ann Arbor, MI

Abstract: Hippocampal dentate granule neurons are sustainably generated from adult neural stem cells (NSCs) in the mammalian brain. The local niche and environment regulate the fate specification of adult NSCs. Toll-like receptors (*TLRs*) have been known to play an important role in adult neurogenesis in the hippocampus. However, the role of *IKKβ*, a downstream molecule of *TLRs*, is not understood in adult neurogenesis. To investigate the role of *IKKβ* in adult neurogenesis, we used tamoxifen inducible GFAP-CreERT2/$IKK\beta^{F/F}$ mice (*IKKβ* conditional knock down mice) in which the *IKKβ* gene is specifically ablated in GFAP- positive neural stem cells. Our results may be summarized as follows.
1. Total *IKKβ* expression in hippocampus and *IKKβ* in Nestin-GFAP positive cells (radial stem cells) were decreased around 50% in GFAP-CreERT2/ $IKK\beta^{F/F}$ mice.
2. NeuroD1 and BDNF expression were increased around 17 and 1.5 times in respectively in *IKKβ* - ablated adult neural stem cells.
3. Ablation of *IKKβ* increased proliferation and differentiation (immature and mature) of adult neural stem cells in the SGZ.
4. Ablation of *IKKβ* increased cell survival of neural stem cells.
5. There's no significant differences in glial differentiation between *IKKβ* deficient mice and vehicle treated mice.
These data suggest that *IKKβ* inhibits adult neurogenesis from the hippocampal dentate gyrus through decreasing proliferation, survival and differentiation of the neural stem cells.

Title: Epigenetic regulation of Kir4.1 following traumatic injury in the developing brain

Authors: S. E. NWAOBI, *M. L. OLSEN
Univ. of Alabama At Birmingham, BIRMINGHAM, AL

Abstract: Traumatic brain injury (TBI) is the leading cause of death and disability in young children in the United States. Once thought to be more resilient to head trauma, new data

suggests pediatric patients are more susceptible than their adult counterparts to secondary injury processes including excitotoxicity, apoptosis, cerebral swelling and vascular damage.
Astrocytes play a critical role in maintaining homeostatic extracellular potassium, $[K^+]_e$, levels within the CNS. Regulation of $[K^+]_e$ is largely mediated by Kir4.1, which is an inwardly rectifying potassium channel. Kir4.1 sets the hyperpolarized resting membrane potential in 'mature' astrocytes; this serves as a source of energy, driving several cellular processes including glutamate uptake. The importance of Kir4.1 in K^+ regulation in the CNS is exemplified in animal models where knocking down or pharmacological inhibition of this channel results in seizures, ataxia and premature death. **Notably, mutations in Kir4.1 in humans are linked to developmental abnormalities characterized by early onset seizures, ataxia and epilepsy.**
Following injury, there are persistent alterations in the biophysical membrane properties of astrocytes, including depolarized resting membrane potentials, reduced Kir4.1 mediated currents and altered extracellular potassium dynamics, suggesting an overall dysregulation of potassium. In human patients, acute increases in $[K^+]_e$ contribute to lesion expansion and edema. Importantly, brain edema is twice as likely to occur in children as adults following TBI and is a major risk factor for death and neurologic impairment. Chronic elevations of $[K^+]_e$ are implicated in neuronal hyperexcitability, seizures and injury induced epilepsy.
We propose that loss of Kir4.1 is a key component in these pathological sequelae and may impact recovery and brain maturation, particularly in the highly plastic, developing pediatric brain. We have developed a pediatric model of TBI to study changes in Kir4.1. By use of lateral fluid percussion injury on postnatal day 14 rats, we demonstrate astrogliosis accompanied by a decrease in Kir4.1 protein following injury.
Despite the importance of Kir4.1 protein for normal brain function, little is known regarding its regulation in the developing brain or after injury. We further propose that K^+ homeostasis is dysregulated following injury due to epigenetic repression of Kir4.1. We hypothesize that post-injury decreases in Kir4.1 are mediated by DNA methylation, providing a potential drug-modifiable mechanism that can be therapeutically targeted to minimize effects of dysregulated K^+.

Title: Knockout of type 2 IP3 receptor in astrocytes enhances cell proliferation in the subgranular zone in dentate gyrus of hippocampus in mice

Authors: W. CHANG[1], H. LI[2], N. ZHANG[1], *S. DING[3]
[1]Univ. of Missouri, Columbia, MO; [2]Universitry of Missouri, Columbia, MO; [3]Univ. of Missouri, COLUMBIA, MO

Abstract: Neurogenesis (birth of neurons) is a process by which neurons are generated from neural progenitor cells. It mainly occurs in two regions of brain, one is the sub-ventricular zone (SVZ) and the other is the subgranular zone (SGZ) in dentate gyrus of hippocampus. Astrocytes release calcium from intracellular stores in response to the activation of different types of Gq-linked G-protein-coupled receptors (GPCRs) through the binding of inositol 1, 4, 5-trisphosphate (IP_3) to its receptor (IP3R). Astrocyte Ca^{2+} has been deemed necessary and sufficient to trigger the release of glio-transmitters, such as ATP and glutamate, to modulate neuronal activity. Several lines of evidence suggest that IP_3R type 2 (IP_3R2) is the primary IP_3R expressed in astrocytes. In this study, we use IP_3R2 knockout mice (KO) mice to determine whether IP_3R2 affects neuronal proliferation in SGZ. We injected Brdu in the KO and WT mice consecutively for 6 days and scarified mice one day after the last injection of Brdu. Then we used immunostaining to study the cell proliferation and lineage commitment of Brdu labeled cells Our results show that IP_3R2 KO mice from age one to 3 month have a larger number of Brdu-labeled cells in SGZ as compared with age-matched wild type (WT) mice. To study the lineage commitment of the Brdu labeled cell, we performed double staining of Brdu/DCX, Brdu/NeuN, Brdu/GFAP. We find IP_3R2 KO mice have higher percentage of Brdu/DCX, Brdu/GFAP double labeled cells, but lower NeuN/Brdu double labeled cell. Furthermore, we studied survival of Brdu labeled cells. As IP_3R2 is mainly expressed in astrocytes, our study suggests that astrocytes may play an important role in adult neurogenesis through IP_3R-mediated calcium signaling pathway.

Title: Effect of epoxomicin administration in a epilepsy model (amigdaloid-kindling) in rat.

Authors: *M. H. CERÓN, SR, E. GONZALEZ, J. FRANCO, J. MARTINEZ, M. RUBIO, V. CUSTODIO, C. PAZ
Neurofisiología, Inst. Nacional De Neurología Y Neurocirugía, Mexico, Mexico

Abstract: Epilepsy is a chronic disease characterized by repetitive crisis caused by an excessive discharge of the neuronal cells and it is well described that many etiologies can cause it. Amigdaloid-kindling has been proposed for it study. It has been demonstrated experimentally that astrocytosis occurs in different cerebral structures due to recurrent seizures, but little is known about the role of this phenomenon in epilepsy. Because it has been described that epoxomicin
administration inhibits the astrocyte response, in this work we wanted to assess its effect in amigdaloid-kindled rats as well as in the changes in electrographic activity and conductual states of this model. In order to achieve our objectives we implanted in wistar male rats both an amigdala-electrode for the kindling induction and a cannula through which we administered intra-ventricular epoxomicin in increasing doses (50, 126, 312 µM). After seven days of post-operative recovery the rats were daily stimulated until they reached the conductual state 5 described by Racine (1972) corresponding by tonic-clonic generalized seizures. Once this state was observed, the rats were injected with epoxomicin. Our results showed an epoxomicin dose-dependent increase in the afterdischarge duration compared with the control and sham group and we also found that the higher dose group (312 µM) showed ataxia, lethargy, spontaneous seizures and death. Therefore we can conclude that there is a dose-related response in the increasing duration of the afterdischarge, supporting the role of the astrocytes as a epileptic modulators, and that high-dose epoxomicin intra-ventricular administration can be the lethal dosage in rats.

Title: SNARE-dependent vesicular release of neuroactive molecules from astrocytes modulates the structure of the node of Ranvier

Authors: H. LEE, H. WAKE, P. R. LEE, *R. FIELDS
NICHD, NIH, BETHESDA, MD

Abstract: The node of Ranvier, which increases conduction velocity of action potentials, is a key element of information processing in the brain. Astrocytes, which are a major glial cell in the central nervous system, surround nodes to maintain appropriate ion concentration. However, regulation of nodal development and organization by astrocytes and the consequences for information processing remain unresolved. Recently, it has been shown that astrocytes modulate neuronal activity by releasing neurotransmitters at neuronal synapses. We have utilized transgenic mice that express an inducible dominant negative SNARE domain in astrocytes (Courtesy of Ken D. McCarthy) to determine whether release of synaptic vesicles from astrocytes affects formation of the node of Ranvier. These mice enable us to impair SNARE dependent vesicular release in astrocytes in early postnatal life when nodes of Ranvier are being formed. Astrocytic specific expression of the transgene resulted in an enlargement of the nodal gap at nodes of Ranvier. This finding was observed in optic nerves and corpus callosum in the brain. G-ratio was increased in the optic nerve of transgenic mice, indicating that myelin thickness was reduced. Our results suggest that SNARE-dependent vesicular release from astrocytes modulates nodal formation and myelination. This could alter saltatory conduction along myelinated axons and greatly affecting information processing in the brain.

Title: Chondroitin sulfate proteoglycan-positive glial cells in the human amygdala and entorhinal cortex: Anatomical distribution in relationship to axonal pathways

Authors: A. SANTOS, A. BOYER-BOITEAU, H. PANTAZOPOULOS, M. MARKOTA, *S. BERRETTA
Translational Neurosci. Lab., Mrc3- McLean Hosp., Belmont, MA

Abstract: Recent results show that a distinct subpopulation of glial fibrillary acidic protein (GFAP)-positive glial cells in the human temporal lobe strongly expresses chondroitin sulfate

proteoglycans (CSPGs). CSPGs are main components of the extracellular matrix, known to regulate developmental and adult neural functions including axonal outgrowth and plasticity. In the healthy human brain, CSPG-positive glial cells have a distinct, highly segregated, and interindividually consistent, pattern of anatomical distribution within restricted subregions of the amygdala and entorhinal cortex. In subjects with schizophrenia, CSPG-positive glial cells were found to be markedly increased in these regions, raising the possibility that these cells may play a role in the pathogenesis of this disorder. Characterization of CSPG-positive glial cells in the human brain is thus necessary to the understanding of the pathophysiological significance of these abnormalities. With this study we tested the hypothesis that the distinct distribution of CSPG-positive glial cells in the human amygdala and entorhinal cortex may be linked to that of incoming axonal pathways. To test this hypothesis, distinct fiber markers, i.e. myelin (Black Gold II; 2',3'-cyclic nucleotide 3' phosphodiesterase (CNPase)) and p75 (a putative marker for cholinergic fibers) were combined with CSPG labeling in medial temporal lobe sections from human subjects (n=3). Myelin-positive fibers were abundant within the amygdala and the entorhinal cortex. CSPG-positive glial cells were located within myelin-rich areas surrounding the central nucleus of the amygdala and the ventral portion of the cortical nucleus. In the entorhinal cortex, myelinated fibers course in bundles running perpendicular to the pial surface but become parallel to it when they reach layer II. CSPG-positive glial cells were highly enriched within dense portions of these parallel coursing myelinated fibers. Putatively cholinergic, p75-labeled fibers form bundles coursing dorsoventrally within the lateral portion of the amygdala, and then disperse along the ventral amygdala border. CSPG-positive glial cells were strongly associated with p75-positive fiber bundles. Together, these results support the hypothesis that the location of CSPG-positive glial cells within the human amygdala and entorhinal cortex may be linked to the distribution of distinct incoming pathways. This spatial relationship is consistent with a key role of CSPGs in axonal guidance and raises the possibility that CSPG-positive glial cells may contribute to a disruption of neural connectivity in schizophrenia.

Title: Transcriptional profiling of astrocyte-specific mRNAs in conditional Fgfr1 mutants

Authors: *K. M. SMITH, R. R. H. DEEGAN, F. M. VACCARINO
Yale Univ., NEW HAVEN, CT

Abstract: Fibroblast growth factors (Fgfs) and several of their receptors (Fgfr) are expressed by astrocytes and astrocytic stem cell lineages of the developing and adult CNS. We previously showed that conditional inactivation of Fgfr1 in neuronal and astrocyte progenitors of the dorsal telencephalon results in locomotor hyperactivity. However, it was not known whether this effect was due to loss of Fgfr1 in glia or neurons. To address this question, we have performed tamoxifen-inducible inactivation of Fgfr1 in postnatal astrocytes (Postnatal day 14-17, 60 mg/kg i.p.) using the hGFAP-CreERT2 (GCE) transgene. Loss of Fgfr1 in postnatal astrocytes results in locomotor hyperactivity, as was seen with loss of Fgfr1 in glial and neural progenitors. Loss of Fgfr1 in postnatal astrocytes also resulted in decreased anxiety on the elevated plus maze test in both embryonic and postnatal mutants. No differences in learning were observed on a modified one-day morris water maze test. In order to identify molecular targets for the actions of Fgfr1 in astrocytes, we have crossed the ALDH1-L10a GFP BAC into the embryonic Fgfr1 knockout line in order to perform mRNA BACTRAP experiments. Transcripts from the cortex and hippocampus of control and Fgfr1 knockout mice were hybridized to Illumina bead array mouse whole genome expression arrays. Ingenuity pathway analysis (IPA) was performed on the expression array data to examine which biological pathways are disrupted by loss of Fgfr1. In the cortex, IPA analysis identified oxidative phosphorylation and mitochondrial dysfunction as top canonical pathways that are significantly altered in Fgfr1 mutants. In the hippocampus, glucocorticoid receptor signaling, NF-κB signaling, and PTEN signaling were identified as top canonical pathways that were significantly altered.

Title: Endothelin-1 regulates Jagged/Notch signaling to inhibit remyelination

Authors: *T. R. HAMMOND[1,2], A. GADEA[3], A. AGUIRRE[4], V. GALLO[3,2]
[1]Childrens Natl. Med. Ctr., Washington, DC; [2]George Washington Univ., Washington, DC; [3]Children's Natl. Med. Ctr., Washington, DC; [4]SUNY-Stony Brook, Stony Brook, NY

Abstract: Multiple sclerosis (MS) results in demyelinated lesions throughout the central nervous system. In response to demyelination, oligodendrocyte progenitor cells (OPCs) repopulate the lesion and begin to differentiate into mature myelinating oligodendrocytes (OLs). Some lesions, however, fail to remyelinate for unknown reasons. The Jagged1/Notch1 pathway has been previously shown to attenuate OPC development in demyelinated lesions. Here we show that the neuropeptide, endothelin-1 (ET-1), induces an upregulation of Jagged1 expression in cultured astrocytes, which is blocked by pan-endothelin-receptor (ET-R) antagonist PD142,893. We also show that ET-1 pre-treated astrocytes inhibit OPC differentiation in a co-culture system. To investigate the effects in vivo, we used focal injections of lysolecithin (LPC) into the mouse corpus callosum/cingulum to induce focal demyelination. In LPC-injected mice we found that ET-1 levels are upregulated near the lesion, and that ET-1 is expressed by astrocytes at high levels at 3 and 7 days post lesion (dpl). In Western blot analysis of micro-dissected tissue we saw increases in ET-1 at 3 dpl, and a peak in Jagged1 expression at 7 dpl. We also saw increases in Notch intracellular cleaved domain (NICD) expression at 7dpl. Next, we investigated cell specific activation of Notch1 in demyelinated lesions using a transgenic Notch reporter mouse (TNR). We found that Notch1 signaling is activated in remyelinating lesions around 7 dpl, and that Notch1 is mainly activated in oligodendrocyte lineage cells (CC1+ and NG2+). To determine if ET-1 directly influenced Notch1 activation, we infused the ET-R pan-antagonist PD142,893 into the lesion following demyelination and found a decrease in the number of EGFP+ TNR cells. Finally, longer term infusion of ET-R antagonists led to increased numbers of mature oligodendrocytes and increased levels of myelin proteins. Altogether these data show that ET-1 regulates Jagged1 expression in astrocytes, and that this leads to activation of Notch1 in demyelinated lesions. Activation of Notch1 in demyelinated lesions inhibits OPC differentiation and Notch is activated throughout the oligodendrocyte lineage, not just in OPCs. These data show that ET-1 is a major factor that modulates Notch1 signaling during remyelination to inhibit differentiation of oligodendrocytes, and to prevent remyelination. Title: EphrinB1/EphB receptor signaling in the adult mouse hippocampus following severe traumatic brain injury

Authors: *A. M. NIKOLAKOPOULOU[1], A. OBENAUS[2], I. M. ETHELL[1]
[1]Biomed. Sci., Univ. of California Riverside, Riverside, CA; [2]Pediatrics, Loma Linda Univ., Loma Linda, CA

Abstract: Molecular and cellular mechanisms of neuron-glial interactions that regulate brain repair following traumatic brain injury (TBI) have attracted the attention of many investigators. Recent studies have identified an up-regulation of many genes and molecules in reactive astrocytes that may promote or hinder regeneration of brain circuits after brain injury. Here, we focus our studies on the involvement of ephrinB1/EphB2 receptor signaling in reactive synaptogenesis and brain repair after severe TBI. EphrinB1 acts as a ligand for the EphB receptors activating intracellular signaling pathways which participate in cell adhesion, axon guidance, stem cell proliferation and synaptogenesis. We tested ephrinB1 expression by immunohistochemistry at 1, 3 and 7 days post severe TBI in a controlled cortical impact model. We observed a significant increase in ephrinB1 expression in hippocampal astrocytes. EphrinB1 upregulation was noted in reactive astrocytes 3 days after TBI in the hippocampus including the stratum radiatum and the stratum lacunosum-moleculare, whilst the hilus of the dentate gyrus showed a moderate increase in the number of GFAP positive astrocytes and ephrinB1-expressing cells. Seven days post-injury, we also observed additional upregulation in ephrinB1 expression in astrocytes as well as non-glial cells within the hilus. Surprisingly, the contralateral hippocampus also exhibited a significant increase in ephrinB1 expression in astrocytes at synaptic sites one day post TBI that peaked at 3 days after injury to return to normal levels at seven days after TBI. Interestingly, we see no astrocytic expression of ephrinB1 in the cortex, suggesting that astrocytic upregulation of ephrinB1 is specific to the hippocampus. We have also examined ephrinB1 mRNA expression following the TBI and we are currently investigating the effects of the ephrinB1 up-regulation on EphB receptor signaling in neurons. Furthermore, we are testing the effects of specific ephrinB1 ablation in astrocytes on reactive synaptogenesis and regeneration following TBI in the hippocampus of conditional ephrinB1 knockout mice. Our studies demonstrate that reactive astrogliosis in the adult hippocampus is followed by an early upregulation of ephrinB1 after TBI in regions of ongoing synaptogenesis and neurogenesis/gliogenesis. Interestingly, the non-injured hippocampus is also affected showing an immediate response to injury by increasing microglia activation, astrogliosis and ephrinB1 expression, suggesting that ephrinB1 may play a neuroprotective role in the brain by affecting neuron-glial interactions.

Title: Neuroinflammatory profile and astrocytic morphology in chronic cyclosporine treated rats.

Authors: M. M. CARARO[1], D. G. SOUZA[2], D. Z. ANDREOTTI[1], L. RODRIGUES[2], L. S. LIMA[1], M. ACHAVAL[3], L. V. PORTELA[2], D. O. SOUZA[2], *C. SCAVONE[1], A. E. BÖHMER[1]

Abstract: Cyclosporine (CsA) dependent neurotoxicity occurs in up to 60% of transplant patients and the clinical predisposition and mechanisms of CsA-induced neurotoxicity remain controversial and poorly understood. Cerebrovascular complications are most frequent in transplanted patients treated with CsA and we already showed that chronic CsA treatment altered biochemical parameters related to cardiovascular and cerebrovascular risk factors. Ischemia process, excitotoxicity and oxidative stress activated microglial cells and astrocytes which in turn react secreting cytokines and chemokines. This process results in neuronal cell death and increased injury to the ischemic area. Since inflammatory signaling is involved in all stages of schemic cascade, the present work investigated the release of cytokines and chemokines related to ischemic brain injury and the astrocytes morphology of the hippocampus of rats submitted to a chronic CsA treatment. Adult male Wistar rats were divided in control group (received vehicle - corn oil), and treated group received 15 mg/kg, by daily gastric gavage during 8 weeks. Cytokines and chemokines were measured on hippocampus, striatum and cortex and astrocytic cell bodies and processes were identified in the CA1 *stratum radiatum*. CsA treated rats showed increase expression of RANTES, MCP1, Gro/KC, IL-1β and IL-12. Quantitative results showed that the number of astrocytes and glial fibrillary acidic protein (GFAP) density were not affected by CsA treatment. However CsA treatment decreased the number of fusiform astrocytes. At the same time, the astrocytes that predominate at CsA treated rats presented an intermediate shape,

between the fusiform and stellate ones. Considering the key importance of astrocytes in controlling the number and function of neuronal synapses and blood flow in the brain, they are capable to change their shapes due to cerebral insult. The increase expression of pro inflammatory cytokines and chemokines related to ischemia and stroke may give rise to chronic neuroinflammation which has been implicated in several neuropathologies.

Title: MicroRNA-338 regulates the axonal expression of multiple nuclear-encoded mitochondrial mRNAs encoding subunits of the oxidative phosphorylation machinery.

Authors: A. N. KAR[1], A. S. ASCHRAFI[1], O. NATERA-NARANJO[1], M. A. MACGIBENY[1], A. E. GIOIO[1], *B. B. KAPLAN[2]

Abstract: microRNAs (miRNAs) constitute a novel class of small, non-coding RNAs that act as post-transcriptional regulators of gene expression. Remarkably, it has been shown that these small molecules can coordinately regulate multiple genes coding for proteins with related cellular functions. Previously, we reported that brain-specific miR-338 modulates the axonal expression of Cytochrome c oxidase IV (COXIV), a nuclear-encoded mitochondrial protein that plays a rate-limiting role in the assembly of the mitochondrial enzyme complex IV of oxidative phosphorylation. Moreover, miR-338-mediated modulation of axonal COXIV mRNA levels resulted in alterations in ATP synthesis and axonal function (Aschrafi et al., 2008). Here, we report that, similar to the COXIV mRNA, the 3'UTR of ATP synthase subunit 9 (ATP5G1), a component of the mitochondrial enzyme complex V, contains a putative miRNA-338 binding site. Using Campenot-compartmentalized cultures of superior cervical ganglion neurons, we show that modulation of miR-338 levels in the axon results in alterations in both COXIV and

ATP5G1 mRNA and protein levels. Importantly, miR-338-mediated modulation of local COXIV and ATP5G1 expression has a marked effect on cytosolic and mitochondrial ROS levels in the axons as measured by 5-(and-6)-carboxy-2',7'-dichlorodihydrofluorescein diacetate (H2-DCFDA) and MitoSOX-Red fluorescence intensity, respectively. Additionally, modulation of axonal miR-338 levels affects the growth of the axon in part by altering local expression of COXIV and ATP5G1. These findings point to a mechanism by which miR-338 can modulate local energy metabolism through the coordinate regulation of the expression of multiple nuclear-encoded mitochondrial mRNAs in the axon.

Title: Differential effects of chronic mitochondrial dna depletion on schwann cells and drg neurons

Authors: V. IDIKUDA[1], A. ISAAC[2], A. BHUSHAN[1], *J. C. LAI[3]
[1]Biomed. and Pharmaceut. Sci., [2]Biomedicl and Pharmaceut. Sci., [3]Idaho State Univ., POCATELLO, ID

Abstract: Mitochondria constitute one of the most dynamic organelles in mammalian cells and play multiple physiological and pathophysological roles in all neural cell types. Because aberrations in mitochondrial DNA have been implicated in neurodegenerative diseases, we have developed chronic mitochondrial DNA (mtDNA) depletion models in vitro employing dorsal root ganglion (DRG) neurons and Schwann cells to facilitate elucidation of mitochondrial dynamics in various peripheral neuropathies. Our models allow us to investigate the hypothesis that neurons and Schwann cells are differentially susceptible to mtDNA depletion. Our ongoing studies have demonstrated that in both DRG neurons and Schwann cells, expression of NADH dehydrogenase subunit 6 (ND6) was inhibited sooner that of cytochrome c oxidase subunit 2 (COX2) as their mtDNA was gradually depleted. Consistently with our hypothesis, we noted that expression of both ND6 and COX2 was inhibited in Schwann cells earlier than that in DRG neurons. We have also observed biphasic changes in their expression of hexokinase 2. Thus, our

findings may have pathophysiological implications in the role(s) of mitochondrial metabolism/dynamics in Schwann cell and DRG neurons in peripheral neuropathies.

Title: Inhibition of glutamine synthesis induces glutamate dehydrogenase-dependent ammonia fixation into alanine in co-cultures of astrocytes and neurons

Authors: *S. DADSETAN[1], E. KUKOLJ[1], L. K. BAK[1], M. SØRENSEN[2,3], S. KEIDING[2,3], H. VILSTRUP[3], P. OTT[3], R. LEKE[4], A. SCHOUSBOE[1], H. S. WAAGEPETERSEN[1]

Abstract: Hyperammonemia is a major etiological factor in the development of hepatic encephalopathy, a neuropsychiatric syndrome occurring secondary to liver failure. Brain ammonia detoxification is believed to occur primarily in astrocytes by glutamine synthesis through glutamine synthetase (GS) and it has been proposed that elevated glutamine levels observed during hyperammonemic conditions is the principal cause leading to astrocyte swelling and concomitant cerebral edema. Interestingly, administration of methionine sulfoximine (MSO), which specifically inhibits GS ameliorates astrocyte swelling and brain edema. Recent studies using neuronal and astrocytic co-cultures have indicated that ammonia may be detoxified not only by incorporation in glutamine but also by the concerted action of glutamate dehydrogenase (GDH) and alanine aminotransferase (ALAT) leading to trapping of ammonia in alanine. The aim of this study was to investigate if the GS inhibitor MSO enhances alanine synthesis by blocking the GS-dependent ammonia scavenging process. Co-cultures of neurons and astrocytes were incubated for 2.5 h with [U-13C]glucose in the absence and presence of 5 mM NH4Cl and 10 mM MSO. Furthermore, incubations with increasing concentrations of 15NH4Cl (1 - 5mM) was performed in the absence and presence of MSO in the same co-culture system. Exposure of co-cultures to [U-13C]glucose in combination with ammonia did not lead to an increased amount of alanine and glutamine intra- and extracellularly. However, 13C labeling in alanine from [U-

13C]glucose was significantly increased in the presence of ammonia and cultures exposed also to MSO exhibited a dramatic increase in content and 13C incorporation of alanine, while the same parameters were decreased for glutamine. Thus, it was demonstrated that inhibition of GS enhances the activity of the alanine synthesizing pathway in this culture system, representing an ammonia scavenging process alternative to the glutamine synthesizing pathway. These results are supported by incubation studies performed with 15NH4Cl, clearly demonstrating a dose-dependent fixation of 15NH4 into alanine together with increased 15N enrichment in glutamate. This provides direct evidence of ammonia being detoxified by the concerted action of GDH and ALAT. Our data points to the potential of GS inhibitors as novel drugs to ameliorate the astrocyte toxicity induced by hyperammonemia.

Title: Systemic administration of tempol, an antioxidant agent, attenuates the increased conditioned emotional response induced by restraint-stress

Authors: *A. FEDOCE[1], S. F. LISBOA[2], L. B. M. RESSTEL[3]
[1]Univ. of São Paulo- Sch. of Med. of Ribeirão Preto, Ribeirão Preto, Brazil; [2]Dept. of Pharmacol., Sch. of Med. of Ribeirão Preto Univ. of São Paulo, School of Medicine of Ribeirão Preto, Brazil; [3]Univ. of São Paulo, chool of Medicine of Ribeirão Preto, Brazil

Abstract: Objectives: Stress is a risk factor for the development of affective disorders, such as anxiety and depression. The organism response to stress leads to neurochemical and behavioral changes that may be associated with oxidative stress. Recent evidences suggest that anxiolytic

drugs may have antioxidant properties. The hypothesis of the present study was that systemic administration of 4-hydroxy-2, 2, 6, 6-tetramethylpiperidine 1-oxyl oxil (Tempol), a superoxide dismutase (SOD) mimetic, reduces the consequence of a stress situation evaluating the contextual conditioned emotional responses. Methods. Male Wistar rats (230-270 g) were divided in two groups: control or restrained for 3 h (acute stress). These animals received Tempol (5 or 10 mg/kg, i.p.) 30 minutes before the restraint-stress (RS). Twenty four hours later animals were submitted to the contextual fear conditioning (3 electrical foot shocks, 0.8 mA, 2 s). After this, a polyethylene catheter was implanted in the femoral artery for cardiovascular recordings. 24h later the animals were re-exposed to the chamber, but without shock presentation, and during this period the freezing behavior and the cardiovascular activity were continuously acquired. Results: The RS increased freezing behavior during re-exposition to the aversive chamber (non-stressed vehicle: 55 ± 1.5 % vs stressed vehicle: 86 ± 2.7%; $F_{1,29}=6.4$, $P<0.02$). In addition, there was significant effect the Tempol ($F_{2,29}=100.7$, $P<0.001$) which was only observed on stressed animals ($F_{2,29}=74.4$, $P<0.001$). Both doses of Tempol attenuated freezing behavior in stressed rats (veh: 86.4±2.7%; 5 mg/Kg: 29.2 ± 1.1%; 10 mg/Kg: 22.5 ± 3.4%; $F_{2,14}=171.4$, P0.05, n=2-6/group). The RS also increased the cardiovascular response during re-exposure to the chamber (MAP: $F_{1,150}=124$, $P<0.0001$ and HR: $F_{1,150}=102$, $P<0.0001$, n=5-6/group). In addition, treatment with both dose of tempol attenuated this effect (5 mg/Kg - MAP: $F_{1,135}=118$, $P<0.0001$ and HR: $F_{1,135}=116$, $P<0.0001$and 10 mg/Kg - MAP: $F_{1,150}=154$, $P<0.0001$ and HR: $F_{1,135}=192$, $P<0.0001$, n=5-6/group).
Conclusion: The present results showed that the increase of behavioural and cardiovascular responses during re-exposure to an aversive context observed in stressed animals is attenuated by systemic administration of an antioxidant agent before the stress session. Our findings suggest that acute stressors could sensitize the animal to a subsequent aversive condition by increase oxidative state.

Title: Effects of a high fat diet on brain metabolism in rats: An *in vivo* 1H-MRS study

Authors: *J. A. STANFORD[1], J. L. HARRIS[2], H.-W. YEH[3], I.-Y. CHOI, PhD[2], W. M. BROOKS[2]

Abstract: Although aging is the primary risk factor for developing Alzheimer's disease (AD) and Parkinson's disease (PD), regular consumption of a high-fat diet has been shown to increase the risk for these neurodegenerative disorders. Despite this, little is known about how neuronal glucose regulation, neurotransmission and metabolism are affected by a high fat diet. While preclinical studies using invasive methods have reported increased neuronal markers of inflammation and oxidative stress following a high fat diet, non-invasive brain imaging methods allow for longitudinal studies with more translational utility. In this study we used high field, short echo time proton magnetic resonance spectroscopy (^{1}H-MRS) to quantify ~20 brain metabolites in the hippocampus and striatum of young adult rats following four months on either normal chow or a high fat diet (60% calories from fat). We evaluated markers related to inflammation, oxidative stress, edema, free fatty acids, bioenergetics and neurotransmission under fasting and fed conditions. We measured decreased total creatine and increased glutamine in both the hippocampus and striatum of high fat-fed rats under non-fasting conditions. These results indicate altered metabolic homeostasis in nuclei related to AD and PD. They also support the utility of ^{1}H-MRS in preclinical studies.

Title: Mitochondrial gene copy numbers are reduced in hippocampal pyramidal neurons from Alzheimer's disease cases

Authors: *A. C. RICE, J. P. BENNETT, Jr
Dept Neurol., Virginia Commonwealth Univ., RICHMOND, VA

Abstract: Mitochondrial dysfunction has been implicated as a causal factor in neurodegeneration in Alzheimer's Disease (AD). Most studies use tissue homogenates, which contain multiple cell types, mainly glia. We used the Arcturus laser capture microdissection system to isolate hippocampal pyramidal neurons from AD cases and compared these to pyramidal neurons isolated from hippocampi of control cases matched for age and postmortem interval . Pyramidal neurons for capture were identified in cresyl violet stained, fresh-frozen hippocampal cryostat sections fixed briefly in ethanol. Multiplex quantitative PCR was used to amplify 4 genes in the minor and major arcs of the mitochondrial genome (12S rRNA, ND2, CO3, ND4). Mitochondrial DNA gene (mtDNA) copy numbers in extracts of captured neurons were derived from a standard curve generated by simultaneous multiplex qPCR of purified, circular human mtDNA. We found a decrease in population distribution of mtDNA gene copy numbers in AD pyramidal neurons compared to controls. Decreased mtDNA gene copy numbers likely derive from decreased mitochondrial mass and imply decreased mitochondrial respiratory function. This mitochondrial deficiency likely results from impaired mitochondrial biogenesis signaling and produces impaired respiration, which we recently reported in frontal cortex samples from the same AD cases. Our findings support the hypothesis that hippocampal pyramidal neurons from AD cases have impaired mitobiogenesis and decreased mitochondrial function, which would increase their vulnerability to early death in AD.

Title: Monocarboxylate transporter 1 (MCT1) is critical for regeneration in peripheral nerves

Authors: A. TSINGALIA[1], S. LENGACHER[2], L. PELLERIN[3], P. MAGISTRETTI[2], J. D. ROTHSTEIN[1], *B. M. MORRISON[1]
[1]Neurol., Johns Hopkins Univ., Baltimore, MD; [2]Univ. de Lausanne, Lausanne, Switzerland; [3]Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland

Abstract: Axons, and particularly regenerating axons, have high metabolic demands in order to maintain critical functions such as axon transport and membrane depolarization. Though some of the required energy likely comes from extracellular glucose and ATP generated in the soma, we hypothesize that some of the energy may be supplied locally by lactate. Unlike glucose that requires glycolytic enzymes to produce pyruvate, lactate can be converted directly to pyruvate by lactate dehydrogenase and transported into mitochondria for oxidative metabolism. In order to be transported across membranes, lactate requires specific monocarboxylate transporters (MCTs), the most abundant of which in the nervous system is MCT1. If MCT1 and lactate are critical for nerve function and regeneration, we hypothesize that MCT1 heterozygote null mice, which appear phenotypically normal despite having approximately 40% MCT1 as compared to wild-type littermate mice, will have reduced capacity for regeneration following nerve injury. To investigate this, adult MCT1 heterozygote null mice or wild-type mice underwent unilateral sciatic nerve crush in the proximal thigh. We found that regeneration of the sciatic nerve, as measured by recovery of compound muscle action potentials (CMAP) in the lateral plantar muscles following proximal sciatic nerve stimulation or quantification of axons in distal sural and tibial nerves, was delayed from a median of 21 days in wild-type mice to greater than 38 days in MCT1 heterozygote null mice. In fact, half of the MCT1 heterozygote null mice had no recovery of CMAP by the endpoint of the study at 42 days, while all of the wild-type mice had recovered. In addition, the maximal amplitude of CMAP recovery in MCT1 heterozygote mull mice was reduced from a mean of 3mV to 0.5mV. Our experiments show that lactate supplied through MCT1 is necessary for nerve regeneration. Experiments are underway to determine the mechanism by which axon regeneration is reduced and whether loss of MCT1 prevents nerve regrowth directly due to reduced energy supply to axons or indirectly by dysfunction of perineurial cells that normally express MCT1.

Title: Kinetic studies on the inhibition of creatine kinase activity by organotellurium compound in cerebral cortex of rats

Authors: *R. B. DE ANDRADE, SR[1], T. GEMELLI[1], D. ROJAS[1], R. GUERRA[2], C. FUNCHAL[2], C. WANNMACHER[1]
[1]Federal Univ. of Rio Grande Do Sul, Porto Alegre, Brazil; [2]Ctr. Universitário Metodista, Porto Alegre, Brazil

Abstract: Tellurium (Te) is used in the industry of rubber, metal and of electronic equipments. Te affects a great number of neural processes, such as modulation of the glutamatergic system, memory and myelinization. Few studies have evaluated the interference of tellurium on critical enzyme activities of energy metabolism. Considering that the exposition to Te brings risks for humans and for environment, the objective of the present study was to investigate the kinetic of the in vitro inhibition of creatine kinase (CK) activity caused by a new Te compound, 3-butyl-1-phenyl-2-(phenyltelluro)oct-en-1-one in cerebral cortex of 30-day-old Wistar rats. Rats (n=3-5) were killed by decapitation and the cerebral cortex was dissected and homogenized in TRIS-sucrose buffer. In the kinetic assay, concentrations were: 2; 3 and 6 mM of ADP / 1; 2; 3 mM of phosfocreatine with 30 and 5 min of pre-incubation in absence (controls) or presence at 5 µM or 20 µM of organotellurium and 1 mM of reduced glutathione (GSH). First, competition experiments between organotellurium and the enzyme substrates ADP or phosphocreatine with preincubation of 30 minutes were performed. The Lineweaver-Burk plot was compatible with non-competitive inhibition. This type of inhibition is defined because Km values and Ki values remains approximately constant independently of the concentration of the organotellurium for the two substrates and for the two isoenzymes from mitochondria and cytosolic fractions. Next, the two subcellular fractions were pre-incubated for 5 min with the two concentrations of the organotellurium. The Linweaver-Burk plot was similar for phosphocreatine as substrate, but suggested mixed inhibition, competitive and non-competitive for ADP as substrate in the two subcellular fractions. This type of inhibition is defined because Km varies according the concentration of the organotellurium, as well the Ki. In order to better understand the mixed type of inhibition, we added reduced glutathione (GSH), a known protector of sulfhydryl groups, to the pre-incubation of 5 min. The Lineweaver-Burk plot did not change for phosphocreatine as substrate, but was of the competitive type for ADP as substrate. The higher variation of the values of Km and Ki are compatible with this type of inhibition. These results suggest that the new Te compound inhibits the activity of the CK by two mechanisms: competition with ADP and oxidation of critical groups for the functioning of the enzyme.

Title: Genetic manipulation of mTOR signaling in mouse cerebral cortex

Authors: *H. KASSAI[1], Y. OHNE[1], K. NAKAO[1], T. MAEDA[2], A. AIBA[1]
[1]Grad. Sch. of Med., [2]Inst. of Mol. & Cel. Biosci., Univ. of Tokyo, Tokyo, Japan

Abstract: Mammalian target of rapamycin (mTOR) is an evolutionarily conserved protein kinase, and functions as two distinct complexes, termed mTORC1 and mTORC2. mTOR is activated by amino acids or growth factor stimuli, and plays an important role in many cellular processes such as cell growth and autophagy. In many human cancers, mutations are often found in PI3 kinase-Akt pathway, and TSC1 and 2 are genes responsible for tuberous sclerosis, which causes abnormalities in nervous system, such as brain tumor, epilepsy and autism. Since all these mutations are associated with chronic activation of mTOR pathway, we focused on addressing mTOR functions in these diseases by establishing animal models of chronically activated mTOR pathway. In this study, we used a constitutively active mutant of mTOR, which retains its kinase activity even under starvation conditions, and established two lines of transgenic (Tg) mice which are different in temporal patterns of active mTOR expression; embryonic and postnatal expression (hereafter referred as embryonic-mTOR Tg and postnatal-mTOR Tg mice, respectively). In embryonic-mTOR Tg mice, active mTOR is expressed in dorsal telencephalon from embryonic day 10. These mice are viable and fertile, but cerebral cortex of the Tg mouse is much smaller than that of the control in adulthood. Reduced cortical size in Tg mice was observed as early as embryonic day 12, and cortical progenitor cells progressively underwent apoptosis at this stage. Therefore, embryonic activation of mTOR pathway leads to the depletion of cortical neurons by neuronal progenitor cell death. Next, we established postnatal-mTOR Tg mice, in which active mTOR is expressed in the forebrain after postnatal 7. Postnatal mTOR Tg mice displayed severe growth retardation, having a smaller body size compared to the control. We detected numerous cytoplasmic inclusions in many neurons in postnatal-mTOR Tg cortex. Accumulation of cytoplasmic inclusions was associated with activation of microglial cells. Therefore, postnatal activation of mTOR pathway induces neurodegenerative disease-like phenotype. In summary, mTOR signaling is important for neuronal cell survival in the cerebral cortex.

Title: Histidine administration to female rats during pregnancy and lactation induces behavioral changes and alters enzymes activity of phosphoryltransfer network in cerebral cortex and hippocampus of the offspring

Authors: *D. B. ROJAS, R. DE ANDRADE, T. GEMELLI, V. ANDRADE, L. OLIVEIRA, A. CAMPOS, C. WANNMACHER
Federal Univ. of Rio Grande Do Sul, Porto Alegre, Brazil

Abstract: Histidinemia is a common inborn error of metabolism of amino acids caused by deficiency of histidase activity in liver and skin with consequent accumulation of histidine (His) in plasma and tissues. It is usually considered harmless to the affected patients and their offspring, but some patients and children born from histidinemic mothers have mild neurological disorders. Recent studies have shown that His induces oxidative stress and affects processes of learning / memory. Thus, the aim of this study was to investigate the effect of His load to female rats during pregnancy and lactation on some behavioral parameters in the open-field task and some enzymes of the phosphoryltransfer network in cerebral cortex and hippocampus of the offspring at 21 and 60 days of age. Fourteen 60-day-old Wistar female rats received L-His (0.5 mg/g of body weight) or 0.85% saline administered subcutaneously in the course of pregnancy and lactation. Pyruvate kinase, cytosolic and mitochondrial creatine kinase activities decreased in cerebral cortex and in hippocampus of treated offspring at 21 days of age and this pattern remained at 60 days of age. On the other hand, adenylate kinase activity was reduced in the cerebral cortex and in hippocampus of the offspring at 21 days of age, whereas the activity was increased in the two tissues at 60 days of age. Behavioral results showed that His decreased distance traveled, number of rearings and crossings in the male offspring at 30-day-old, but at 60-day-old the results did not differ from the control group. Our results suggest that administration of His to female rats in the course of pregnancy and lactation may impair phosphoryltransfer network in the cerebral cortex and hippocampus of the offspring and reduce

creatine and pyruvate content, two important antioxidants and neuroprotectors. Oxidative stress caused by L-histidine is a possible mechanism for the decreased enzymatic activity. Moreover, behavioral alterations indicate a decreased exploratory and locomotory activity in the offspring, which can be due to alteration of energy homeostasis and its consequences to brain functioning. Considering that histidinemia is usually a benign condition and little attention has been given to maternal histidinemia, it seems important to perform more studies in the children born from histidinemic mothers. It is possible that histidinemia, usually a benign condition for children exposed to high postnatal levels of histidine, may cause alterations if the brain is exposed to high levels during intrauterine development and breastfeeding.

Title: Inversion of neurovascular coupling after subarachnoid hemorrhage

Authors: M. KOIDE[1], A. D. BONEV[1], M. T. NELSON[1,2], *G. C. WELLMAN[1]
[1]Pharmacol., Univ. of Vermont, Burlington, VT; [2]Inst. of Cardiovasc. Sci., Univ. of Manchester, Manchester, United Kingdom

Abstract: Aneurysmal subarachnoid hemorrhage (SAH) is associated with high rates of morbidity and mortality. The cellular events contributing to SAH-induced ischemic neuronal damage, a major cause of poor outcome, are still elusive. Here we examined the impact of SAH on neurovascular coupling (NVC) in brain slices from control and SAH model rats. Brain slices were loaded with the fluorescent Ca^{2+} indicator dye, fluo-4, and astroctyic endfoot Ca^{2+} concentration and adjoining parenchymal arteriolar diameter were simultaneously measured using two-photon and infrared-differential interference contrast (IR-DIC) microscopy. As

anticipated, neuronal activation by electrical field stimulation (EFS) caused an increase in endfoot Ca^{2+} followed by arteriolar dilation in brain slices from control rats. Remarkably, EFS caused a similar increase in astrocyte endfeet Ca^{2+} but induced vasoconstriction rather than vasodilation in brain slices from day 4 SAH animals. Similarly, Ca^{2+} uncaging in astrocyte endfeet caused vasodilation in control brain slices and vasoconstriction in brain slices from SAH rats. Paxilline, a blocker of large-conductance Ca^{2+}-activated K^+ (BK) channels, greatly diminished both EFS-induced vasodilation and vasoconstriction in brain slices from control and SAH rats, respectively. Interestingly, we also observed an increase in the magnitude of spontaneous astrocytic Ca^{2+} oscillations in brain slices from SAH animals. The peak amplitude of spontaneous astrocytic Ca^{2+} oscillations in brain slices after SAH was ~490 nM compared to ~ 320 nM in brain slices from control animals. Our data are consistent with a model in which SAH increases the amplitude of spontaneous astrocytic Ca^{2+} oscillations leading to increased activity of endfoot BK channels and elevation of basal extracellular K^+ in the restricted perivascular space between astrocytic endfeet and parenchymal arteriolar myocytes. This SAH-induced elevation in basal perivascular K^+ combined with further K^+ efflux stimulated by neuronal activity elevates K^+ above the dilation/constriction threshold, switching the polarity of arteriolar responses from vasodilation to vasoconstriction. This inversion of NVC may contribute to decreased cerebral blood flow and the development of delayed ischemic neuronal deficits following SAH.

Title: Picomolar pituitary adenylate cyclase activating polypeptide (PACAP) potently dilates middle meningeal artery: Potential role in migraine headache

Authors: A. SYED[1], M. KOIDE[1], *V. MAY[2], G. WELLMAN[1]
[1]Dept of Pharamacol, [2]Dept Anat & Neurobiol, Univ. Vermont Col. Med., BURLINGTON, VT

Abstract: Migraine is a debilitating neurological disorder characterized by unilateral pulsating headache that is often accompanied by aura, nausea, photophobia, phonophobia and other neurological symptoms. The underlying mechanism of pain in migraine is still poorly understood. Among several proposed mechanisms, vasodilation of the dural vasculature, specifically the middle meningeal artery (MMA), has been shown to coincide with migraine headache. Neuropeptides, including calcitonin gene-related peptide, contained within the trigeminal sensory and sphenopalatine postganglionic parasympathetic fibers innervating these vessels have been implicated in the process. Recently pituitary adenylate cyclase activating polypeptide (PACAP), a neuropeptide present in trigeminal sensory fibers, has been linked to migraine pain. PACAP is a neurotransmitter and neurotrophic peptide in the secretin, glucagon and vasoactive intestinal peptide (VIP) superfamily and shares some G protein coupled receptor selectivity with VIP. PACAP binds potently and specifically to the PAC1 receptor which may be coupled to multiple intracellular signaling cascades; by contrast, both PACAP and VIP bind with near equal affinity to VPAC1 and VPAC2 receptors coupled principally to adenylyl cyclase. To date the ability of PACAP to relax isolated unpressurized MMA segments pre-contracted with exogenous vasoconstrictors is controversial. The objective of the present study was to examine the ability of PACAP to induce dilation of pressurized rat MMAs ex-vivo. Isolated segments of rat MMA were cannulated on glass micropipette and pressurized to an intravascular pressure of 40 mmHg. At 40 mmHg, MMAs developed intrinsic myogenic tone, representing ~40% decrease in diameter. Under these conditions, PACAP potently dilated MMAs with an IC_{50} of ~1 pM. In contrast, VIP was found to be ~1000-fold less potent (IC_{50} ~1 nM). The PAC1 receptor antagonist, PACAP(6-38), abolished MMA dilation caused by picomolar concentrations of PACAP. Cerebral arteries isolated from the brain surface were ~1000-fold less sensitive to PACAP than MMAs. RT-PCR analysis of the cerebral arteries exhibited expression of all 3 PACAP receptor subtypes (PAC1, VPAC1 and VPAC2), however MMAs demonstrated the presence of PAC1 and VPAC2 receptors only. Further, MMAs expressed multiple splice variants of the PAC1 receptor subtype. In summary, our data demonstrate that PACAP is a potent dilator of pressurized MMA ex vivo. MMA dilation in response to picomolar concentrations of PACAP appear to be mediated via activation of the PAC1 receptor. PACAP-induced MMA dilation may play a role in the etiology of migraine headache.

Title: Broad therapeutic window for ONO-2506 in preventing subarachnoid hemorrhage (SAH)-associated cerebrovascular and neurologic dysfunction

Authors: H.-L. XU, C. PAISANSATHAN, F. VETRI, J. WATCHAROTAYANGUL, *D. A. PELLIGRINO
Dept Neuroanesthesia, Univ. Illinois Chicago, CHICAGO, IL

Abstract: We recently observed a substantial loss of pial arteriolar dilating function, as well as impaired neurologic function, at 48 h post-SAH (anterior cerebral artery suture perforation model). Those changes were largely prevented by acute application (30 min post-SAH) of either ONO-2506 (selective S100B inhibitor) or soluble RAGE [decoy peptide for RAGE (receptor for advanced glycation end-products)], indicating that S100B/RAGE engagement plays an important role in the pathogenesis of SAH-induced cerebrovascular dysfunction. In this study, we examined whether delaying inhibitor treatments until 6h post-SAH conferred a similar benefit toward recovering neurologic and pial arteriolar dilating function measured at 48h. We anticipated an extended therapeutic window for ONO-2506 treatment, since the rise in S100B levels in cisternal CSF does not reach its peak until 2 days post-SAH. Rats were randomized into three groups: (1) sham surgical controls; (2) vehicle-treated SAH controls; and (3) ONO-2506-treated SAH rats. Rats in group 3 received 10 mg/kg ONO-2506 ip at 6 h post-SAH, followed by same dosage every 24 h; while animals in groups 1 and 2 were treated with normal saline. Using a closed cranial window system, we measured dilator responses at 48 h after SAH. We observed diminished pial arteriolar responses to hypercapnia, sciatic nerve stimulation (SNS), and topically-applied adenosine (ADO), acetylcholine (ACh), and S-nitroso-N-acetyl penicillamine (SNAP). Treatment with ONO-2506 restored most of the impaired pial arteriolar dilating responses, except the response to SNS. Additionally, a significant improvement in neurologic outcome scores (the lower the score, the greater the impairment) was revealed in ONO-2506-treated animals (neuroscore = 16.67±1.25 vs 11.29±2.66 in vehicle-treated rats). In summary, the results suggest that (1) the S100B inhibitor, ONO-2506, exerts its protective effect toward SAH-related neuropathy by preventing losses in cerebral vascular dilating function; and (2) ONO-2506 treatment is associated with a wide therapeutic window (up to 6 h post-SAH).

Title: Subarachnoid hemorrhage (SAH) induces delayed, but not acute, inversion of neurovascular coupling in rat cortical brain slices

Authors: *A. C. PAPPAS[1,2], M. KOIDE[2], G. C. WELLMAN[2]
[1]Burlington, VT; [2]Univ. of Vermont, Burlington, VT

Abstract:
Pathological changes within the intracerebral microcirculation contributing to the development of delayed neurological deficits following aneurysmal SAH are not well understood. Physiologically, neurovascular coupling (NVC) represents the matching of increased local blood flow to focal increases in neuronal activity. However, we have recently observed inversion of the NVC response from vasodilation to vasoconstriction in brain slices from rats 4 days (d) after the initiation of experimental SAH. The objective of the present study was to determine whether inversion of NVC represents an acute or delayed effect of subarachnoid blood. Experimental SAH was induced in anesthetized adult male rats by injecting 0.5 mL of whole autologous blood into the cisterna magna on two consecutive days. Cortical brain slices were obtained 4 hours (hr), 2 d, 4 d, 7 d and 14 d following the induction of SAH, and from un-operated control animals. Brain slices were loaded with the Ca^{2+} indicator dye, Fluo4-AM. Astrocytic endfoot Ca^{2+} and arteriolar diameter were recorded simultaneously using combined multi-photon and infrared differential interference contrast microscopy. Electrical field stimulation (EFS) was used to evoke neuronal activity. As expected, EFS caused an increase in endfoot Ca^{2+} that preceeded arteriolar dilation in brain slices from control animals. A similar increase in endfoot Ca^{2+} and arteriolar dilation was observed in brain slices 4 hr after induction of SAH. However, brain slices from later SAH time points exhibited EFS-induced increases in endfoot Ca^{2+}, followed by vasoconstriction rather than vasodilation. Our data demonstrate that SAH-induced inversion of NVC does not occur immediately (within the first 4 hours) despite the observed presence of red blood cells in the cortical perivascular space. Further, we found that the delayed inversion of

NVC can last up to 14 d after SAH. These data suggest that the mere presence of extravascular blood is insufficient to directly invert the NVC response. Rather, SAH-induced inversion of NVC is likely due to time-dependent changes within the brain parenchyma following exposure to blood. SAH-induced inversion of NVC may contribute to the development of delayed neurological deficits that frequently occur in patients in the days to weeks following cerebral aneurysm rupture.

Title: Compromise of spinal cord microvasculature in cervical spondylotic myelopathy

Authors: *S. K. KARADIMAS[1,2], W. YU[1], E. MOON[1], M. FEHLINGS[1,2]
[1]Toronto Western Hospital, UHN, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Introduction:
Cervical spondylotic myelopathy (CSM) is the most common cause of spinal cord dysfunction in adults, however little is known about the molecular mechanisms of the disease. Currently little is known regarding the fate of blood vessels and the integrity of the BSCB during chronic cervical spinal cord compression. We hypothesize that progressive compression of cervical spinal cord in CSM compromises the spinal cord microvasculature.
Material and Methods: In the present study we used two different experimental approaches. *Human CSM:* We examined the extravascular expression of fibronectin, as a measure of BSCB permeability and counted the number of Von Willebrand Factor (VWF) positive vessels in post-mortem human spinal cord tissues derived from 8 CSM patients and ten control cases. *Rat CSM:* Complementary studies were conducted in CSM rats (compression group) and in sham operated rats. At 9 weeks post-surgery MRI acquired from the animals of the compression group before and after T1-gadolinium diethylene triamine pentaacetic acid (Gd-DTPA) administration to evaluate *in vivo* the BSCB permeability. Animals were sacrificed at 10 weeks post-surgery. Prior to sacrifice 100 µl of 4% Evans Blue (EB) was injected. The chronic BSCB breakdown reflected by the leakage of fluorescent EB was evaluated rostral and caudal to and at compression

epicenter. Finally, to assess the number of mature vessels in the cervical spinal cord, quantitative confocal immunohistochemistry will be performed on sections labeled with RECA-1 and laminin.
Results: *Human CSM:* Significant increase in number of fibronectin positive vessels and fibronectin positive cells of the
parenchyma in human CSM patients but not in non-CSM controls, suggesting chronic BSCB permeability. Increased von Willebrand factor expression was also seen in human CSM patients, suggesting endothelial cell dysfunction. *Rat CSM:* At 10 weeks post-surgery, the overall EB and fibronectin intensity in the total spinal cord section area of the compression group was found to be statistically significant increased compared to sham operated group ($p=0.008$ and $p=0.021$). Moreover, we
found that the ratio of the relative signal Gd-DTPA intensity between the compression level (C6) and 3 levels above(C3) was 1.5±0.11. Finally, statistical significant decreased number of RECA-1 and laminin positive blood vessels was found at the compression group compared to sham operated group ($p<0.009$ and $p=0.012$).
Conclusion: In conclusion, we report for first time novel evidence indicating chronic BSCB disruption and vascular damage under the chronic progressive compression of the cervical spinal cord in CSM.

Title: FKBP51 shapes stress response and signaling pathways involving protein kinases and autophagy

Authors: N. C. GASSEN, J. ZSCHOCKE, J. HARTMANN, L. KOLLMANNSBERGER, *F. HOLSBOER, M. V. SCHMIDT, T. REIN
Max-Planck-Inst Psychiatry, Munich D-80804, Germany

Abstract: Gene association studies linked FK506-binding protein (FKBP) 51 to psychiatric diseases like major depression and also suggested a connection of FKBP51 with the actions of antidepressants. Furthermore, FKBP51 protein levels have been correlated with the efficacy of antidepressants. While FKBP51 is firmly established as a potent inhibitor of the glucocorticoid

receptor (GR), we here set out to identify novel molecular networks beyond FKBP51's action on GR and to test the relevance of these networks for the actions of antidepressants. We investigated the influence of FKBP51 on protein kinases including Akt; Akt is a key regulator of the PI3K/Akt/mTOR pathway and is thought to be modulated by several antidepressants. We report a specific interaction of FKBP51 and its close homologue FKBP52 with Akt1 and 2, but not Akt 3. FKBP51 recruited the phosphatases PHLPP1 and 2 to Akt1 and 2 leading to dephosphorylation of the latter and thus inactivation of downstream signalling as assessed by phosphorylation of Foxo3a. FKBP52 did not bind to PHLPP1 and 2, and therefore did not affect Foxo3a phosphorylation status as well as other substrates of Akt. FKBP51 also affected targets downstream of the Akt pathway, as exemplified for its impact on autophagy: Analysis of LC3B distribution revealed that ectopically expressed FKBP51 induced redistribution of LC3 into autophagosomal vesicles in rat cortical astrocytes. Furthermore, the levels of beclin1 and LC3B-II were increased. Virtually all of these FKBP51 actions were shared by antidepressants; importantly, the effects of antidepressants were greatly enhanced by increasing FKBP51. Altogether, we put forward the hypothesis that FKBP51 is a crucial determinant of antidepressants' action on Akt/mTOR signaling and downstream physiological processes such as autophagy.

Title: Uncovering roles of monocarboxylate transporter-1 in the cerebellum

Authors: *Y. LEE[1], L. CHAKRAVARTI[1], I. SHATS[1], S. VIDENSKY[1], L. JIN[1], L. PELLERIN[2], P. J. MAGISTRETTI[3], J. D. ROTHSTEIN[1]
[1]Dept Neurol., Johns Hopkins Sch. of Med., Baltimore, MD; [2]Dept. of Physiol., Univ. of

Lausanne, Lausanne, Switzerland; [3]Brain Mind Institute, Ecole Polytechnique Fédérale de Lausanne, and Ctr. for Psychiatric Neurosci. UNIL-CHUV, Lausanne, Switzerland

Abstract: The cerebellum, as a highly energetic structure, may be particularly susceptible to alterations in metabolic coupling between neurons and glia during development and in disease. Although glucose is considered the primary energy substrate for neurons, neurons can also utilize lactate released by neighboring glia through monocarboxylate transporters (MCTs). MCT-1, one of 14 members of the *SLC16A* family, is a predominant isoform expressed in the nervous system. However, the expression pattern and function of MCT-1 in the cerebellum are still poorly understood.From the analysis of BAC MCT-1 tdTomato reporter mice, we found that oligodendroyctes in the white matter of the cerebellum strongly express MCT-1. In addition, tdTomato expression is detectable in mature, differentiated Purkinje neurons. Migrating progenitors in the external germinal layer strongly express MCT-1 but do not express the glucose transporter found in differentiated neurons, suggesting a metabolic switch during cerebellar development. MCT-1 heterozygous knockout mice display prominent axonopathy in the granular cell layer as well as white matter, suggesting impaired metabolic support of axons by myelinating oligodendroglia via MCT-1. These mice also show mild Purkinje neuron degeneration as evidenced by immunohistochemical analysis, electron microscopy analysis, and behavior tests. Degeneration may be caused by damage of Purkinje axons due to lack of myelin support or loss of MCT-1 in Purkinje neurons. Strikingly, ectopic overexpression of MCT-1 in Bergmann glia and astrocytes also leads to severe Purkinje neuron degeneration and abnormal dendritic morphology as well as hindlimb clasping, suggesting an alteration of metabolic coupling between Purkinje neurons and Bergmann glia. Since glutamate excitotoxicity is thought to contribute to non-cell autonomous cerebellar neurodegeneration in some forms of ataxia, such as spinocerebellar ataxia type 7 (SCA7), and MCT-1 expression is also altered in amyotrophic lateral sclerosis, we investigated whether MCT-1 knockout or ectopic overexpression in Bergmann glia affected glial glutamate transporter expression. qRT-PCR analysis showed marked reduction (~40%) in glutamate aspartate transporter (GLAST) mRNA in the cerebellum in both MCT-1 heterozygous knockout mice and overexpressor mice as compared to control, suggesting that excitotoxicity along with altered metabolite shuttling may contribute to cerebellar degeneration. Taken together, these results indicate that MCT-1 expression in the cerebellum is essential for Purkinje cell integrity and survival as well as axonal homeostasis.

Title: Neuregulin 1 type I ameliorates axonal loss in a mouse model for Charcot-Marie-Tooth-Disease 1A

Authors: *M. W. SEREDA, R. STASSART, R. FLEDRICH, K.-A. NAVE
Max-Planck Inst. Exp. Med., Goettingen, Germany

Abstract: Charcot-Marie-Tooth Disease 1 A is the most common inherited neuropathy caused by a duplication of the peripheral myelin protein of 22kDa (PMP22). CMT1A is a slowly progressive disease, characterized by demyelination, axonal loss and muscle atrophie. A mouse model for CMT1A harbouring additional copies of the Pmp22 gene displays the typical features of the disease such as axonal loss and impaired motor function. Neuregulin1 belongs to a family of transmembrane and secreted growth factors subdivided into three classes according to their extracellular domain. Neuregulin 1 isoforms are essential for survival and proliferation of Schwann cells and Neuregulin 1 type III has been shown to regulate myelin sheath thickness in the peripheral nervous system. In this study, we investigated the role of different Neuregulin 1 isoforms in a mouse model for CMT1A. Neuregulin 1 type III mRNA was found to be downregulated in DRG neurons of Pmp22 transgenic mice, whereas Neuregulin 1 type I mRNA expression levels were increased in DRG neurons. At the age of four month, Pmp22 transgenic mice displayed axonal loss in the sciatic nerve. Crossbreeding of Pmp22 overexpressing mice with Neuregulin 1 type I transgenic animals caused axonal preservation. Moreover, Neuregulin 1 type I Pmp22 double transgenic mice displayed an increase in the compound muscle action potential (CMAP) compared to single Pmp22 transgenic mice. Unexpectedly, Neuregulin 1 type III Pmp22 double transgenic mice showed no axonal preservation.
Analysis of an acute nerve injury model revealed that mice overexpressing the type I isoform of Neuregulin 1 displayed an improved axonal regeneration compared to wildtype controls. Along with the enhanced axonal regeneration, Neuregulin 1 type I transgenic animals depict an improvement in phenotype and CMAP after nerve crush. We conclude, that Neuregulin 1 type I is beneficial for axonal preservation and regeneration in the peripheral nervous system.

Title: Effect of hyperglycemia on white matter microstructural integrity in youth with T1DM

Authors: *J. V. ANTENOR-DORSEY[1], E. MEYER[2], J. RUTLIN[1], D. PERANTIE[1], N. H. WHITE[2], A. ARBELAEZ[2], J. SHIMONY[3], T. HERSHEY[1]
[1]Psychiatry, [2]Pediatrics, [3]Radiology, Washington Univ., SAINT LOUIS, MO

Abstract: Hyperglycemia is hypothesized to affect white matter integrity in the developing brain. Although decreased white and gray matter volumes have been reported in youth with type 1 diabetes (T1DM), the effects of hyperglycemia on white matter microstructural integrity have not been quantitatively assessed during development. Based on previous volumetric findings, we hypothesized that white matter microstructural integrity in the superior parietal lobule and hippocampus would be particularly sensitive to any negative effects of hyperglycemia exposure in youth with T1DM. Diffusion tensor images from a retrospective study of T1DM youth (n=73; mean$\pm$SD age=16.8$\pm$2.9) and their non-diabetic sibling controls (n=30; mean+SD age=15.9$\pm$3.4) were analyzed using two complimentary approaches, region-of-interest and voxel-wise tract-based spatial statistics (TBSS), to quantify white matter microstructural integrity in both *a priori* regions and across the brain. Degree of lifetime exposure to hyperglycemia (lifetime median HbA1c weighted for T1DM duration) and the number of severe hyperglycemia and severe hypoglycemia episodes were estimated from review of patients' medical records, HbA1c levels and parent/youth interviews. Univariate analyses controlling for the effects of age and gender showed that the T1DM group had lower fractional anisotropy (FA) in the superior parietal lobule ($F(1,99)=2.84$, $p=0.007$), but not the hippocampus. The T1DM group also had reduced mean diffusivity in the thalamus ($F(1,99)=22.81$, $p=0.002$) compared to controls. A history of three or more severe hyperglycemic episodes (3+ SHyper) was associated with reduced FA in the superior parietal lobule ($F(5,97)=2.71$, $p=0.008$; 3+ SHyper vs. controls, $p=0.009$) and increased diffusivity in the hippocampus $F(5,97)=2.67$, $p=0.03$; 3+ SHhyper vs. 1-2 SHyper, $p=0.038$). In the TBSS analyses, the T1DM group had lower axial diffusivity across multiple white matter tracks compared to controls. The T1DM group with no prior history of severe hypoglycemia also had reduced mean and axial diffusivity compared to controls. Blood glucose at the time of scan was not different across severe hyperglycemic and hypoglycemic subgroups. These results add microstructural integrity of white matter to alterations observed in the brains of youth with T1DM and highlight the vulnerability of the superior parietal lobule and hippocampus to

glycemic extremes during brain development. Longitudinal analyses will be necessary to determine how these alterations change with age or additional glycemic exposure.

Title: The effect of polychlorinated biphenyl exposure on behavioral development and thyroid status in Sprague-Dawley rat pups: Gestation vs. lactation.

Authors: *D. E. MANKIN[1], E. N. DOVER[1], Z. M. WANG[1], H. C. CROMWELL[2], L. A. MESERVE[1]
[1]Biol. Sci., [2]Psychology, Bowling Green State Univ., Bowling Green, OH

Abstract: Polychlorinated biphenyls (PCBs) are a group of persistent environmental contaminants that are known endocrine disrupting compounds and have been found in placental tissue and breast milk. Incorporation of PCB into the diet of pregnant rats has been shown to alter maternal care as well as motor, sensory, and psychological functions in pups during neurological development. Some of these alterations are thought to result from the ability of PCB to affect thyroid hormone (TH) synthesis, circulation and feedback mechanisms. Proper TH levels are crucial during gestation for proper neurological development. In the present study, a cross-fostering paradigm was used to compare the effects of PCB exposure during gestational development versus exposure during lactation. 32 female Sprague-Dawley rats were used and once pregnant, either placed on a diet containing equal amounts of two PCB congeners (47/77, 25 ppm total) or left on a control diet. After birth, all dams were once again placed on control diets and each litter was either cross-fostered to a dam of the opposite dietary treatment or left with their birth dam. To test for potential developmental deficits, several neurobehavioral tests were conducted on various postnatal days (PNDs). These tests included analysis of ultrasonic vocalization (USV) production (PND 10) following isolation from the dam, conditioned odor preference (COP) on PNDs 12 - 14, open field behavior (PNDs 15 - 16), and grooming behavior

(PNDs 15 - 17). Serum thyroxine (T_4) concentrations were determined on PND 17. PCB exposure increased the number per time of isolation USVs (69%) and line crosses in the open field (122%). During COP testing, pups gestationally exposed to PCB showed an aversion to lemon scent, spending only 29% of their time near it. In contrast, controls failed to show a preference or aversion to the lemon scent. Grooming behavior was also disrupted in rats exposed to PCB, most notably on PND 16. Controls had the highest rate of completed grooming chains (42%) followed by pups that were born to a PCB dam and then cross-fostered to a control dam (27%). Pups remaining with PCB dams, and therefore exposed to PCB both during gestation and lactation, had the lowest rate of completed grooming chains (19%). PCB exposure also significantly reduced T_4 concentrations, with pups remaining with PCB dams showing the most reduction (35%), and those cross-fostered in either direction showing an intermediate reduction (15%) as compared to control pups. Taken together, these data suggest that exposure to small amounts of PCB can cause altered behavioral development regardless of whether exposure occurs during gestation only, lactation only, or both.

Title: Opposing actions of genetic and gonadal sex on affect regulation

Authors: *M. L. SENEY, E. SIBILLE
Dept. of Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Sexual dimorphism in major depressive disorder (MDD) is well established, but the mechanism(s) underlying increased female vulnerability remain unknown. While evidence suggests an influence of adult circulating hormones (*activational hormone effects*), female MDD prevalence is higher across life stages, implying contribution by additional biological factors.

Studies suggest a developmental origin for adult mood, and notably, developmental processes also establish brain sexual dimorphism (*organizational hormone effects, X/Y genetic sex*). We hypothesize that developmental processes contribute to adult female vulnerability to MDD. We used the genetically engineered Four Core Genotype (FCG) mice, in which genetic and gonadal sex are dissociated, to independently examine effects of X/Y genetic sex, developmental hormones, and adult circulating hormones on behavior ($N \geq 12$/group; total $N = 116$). Adult mice were gonadectomized and implanted with a testosterone (T) or blank capsule. Mice were then tested for anxiety-like (elevated plus maze, open field) and anhedonia-/depressive-like (novelty suppressed feeding, sucrose preference) behaviors at baseline and after unpredictable chronic mild stress (UCMS). Dependent measures were analyzed by ANOVA with 3 main effects: developmental gonadal sex, adult hormone treatment, and genetic sex. Genetic male sex increased anxiety-like behavior (XY > XX) and decreased activity (XY < XX), but had no effect on anhedonia-/depressive-like behavior (XY = XX). Presence of testes during development had little effect on anxiety-like behavior or activity (testes = ovaries), but decreased anhedonia-/depressive-like behavior (testes < ovaries). Circulating T decreased anxiety-like behavior (blank > T) and increased activity (blank < T), but had no effect on anhedonia-/depressive-like behavior (blank = T). Consistent patterns were observed under baseline conditions and after UCMS. Genetic sex and circulating testosterone (activational) modulated anxiety-like behavior, whereas developmental gonadal sex (organizational) affected anhedonia-/depressive-like behavior. Hence, in a wild-type male, a surprising dynamic equilibrium between opposing actions of testosterone and XY genetic sex appears to regulate anxiety-like behavior, resulting in lower levels compared to females. The robust dichotomy between increased anxiety-like and reduced locomotor activities has been observed in other systems, including in primates and possibly in humans, and is thought to reflect epistatic phenomena downstream from common genes, for which our data now point to X and Y chromosome genes as potential mediators.

Title: Low doses of ozone altered the regulation of the immune response in rats hippocampus.

Authors: *N. GOMEZ-CRISOSTOMO[1], E. JALPA-HERNANDEZ[2], L. MEJIA-CARMONA[2], S. RIVAS-ARANCIBIA[2]

Abstract: The immune response in the central nervous system (CNS) has been a subject of controversy. Several researches have highlighted the role of cytokines in neurodegeratives processes. Has also been demonstrated that exposure to ozone could suppress or activate the immune response. However, many works only shown the effect of ozone on immune regulation on respiratory system and other systems, nevertheless the effect of ozone on the CNS is poorly understood. In our laboratory we have developed a murine model that produces a chronic and irreversible neurodegenerative process by chronic exposure to low doses of ozone. The aim of this work is to evaluate the inflammatory response generated by exposure to low doses of ozone in hippocampus of rats. Seventy-two Wistar male rats were randomly divided into 6 groups: 1) Control (air), 2) Ozone (O3) for 7 days, 3) O3 for 15 days, 4) O3 for 30 days, 5) O3 for 60 days and 6) O3 for 90 days. Ozone-exposed groups received a dose of 0.25 ppm for 4 hours. Two hours after treatment each group was divided into two subgroups. In the first subgroup, animals were anesthetized and perfused, the brains obtained and processed for immunohistochemistry technique. Second subgroup, animals were anesthetized and the hippocampus dissected for western blot technique for 3-Nitrotyrosine, GFAP, NFkβ, IL-10 and IL-17. Our results showed increased expression of 3-Nitrotyrosine from the 7-day and until 90 days after exposure to ozone. GFAP increases significantly after 30 days exposure to 90 days. NFkβ and IL-17 increased after 60 days to exposure of ozone. IL-10 expression is decreased from 60 to 90 days of exposure to ozone. In conclusions the chronic exposure to low doses of ozone produce oxidative stress state that lead to neurodegenerative processes and a dysregulation of the immune response.

Title: Hematopoietic factors contribute to CNS vascular permeability and microhemorrhage formation in CD8 T cell-initiated blood brain barrier disruption

Authors: *H. JOHNSON[1], Y. CHEN[2], G. SUIDAN[2], J. MCDOLE[2], A. LOHREY[2], L. HANSON[1], F. JIN[1], I. PIRKO[1], A. JOHNSON[1]

Abstract: Blood brain barrier disruption is an integral feature of numerous neurological disorders. A central question in neurological disease is the extent blood-derived factors or stromal tissue contribute to blood brain barrier disruption. Using a variation of the Theiler's murine encephalomyelitis virus (TMEV) model designed to study immune-mediated CNS vascular permeability, we report that despite having indistinguishable CD8 T cell responses and neutrophil infiltration, C57BL/6 mice exhibited increased CNS vascular permeability, microhemorrhage formation, and functional deficits compared to 129 SvIm mice. To investigate the contribution of hematopoietic cells in this model, resistant 129 SvIm mice were reconstituted with either C57BL/6 or autologous 129 SvIm bone marrow. Three-dimensional volumetric analysis of gadolinium-enhanced T1-weighted MRI scans revealed that 129 SvIm mice reconstituted with C57BL/6 bone marrow but not autologous bone marrow exhibited a profound increase in CNS vascular permeability. 129 SvIm mice reconstituted with C57BL/6 bone marrow also presented with increased microhemorrhage formation, as measured by T2*-weighted MRI, and functional deficits when compared to 129 SvIm mice receiving 129 SvIm syngeneic bone marrow transfer. We conclude that C57BL/6 susceptibility to CNS vascular permeability, microhemorrhage formation, and functional deficit is transferable with the bone marrow compartment, demonstrating that hematopoietic factors contribute to CNS vascular permeability and microhemorrhages in immune-mediated fatal blood brain barrier disruption.

Title: Attenuation of experimental autoimmune encephalomyelitis by high mobility group box 1 fusion protein

Authors: *X. PARILLON[1], L. GUO[2], S. HAN[2]
[1]Immunol. and Pathology, [2]Baylor Col. of Med., Houston, TX

Abstract: High Mobility Group Box 1 (HMGB1) is a ubiquitously expressed protein that has been linked to central nervous system inflammation. HMGB1 expression is elevated in the serum and tissues of patients with multiple sclerosis (MS). Currently, many of the therapeutics to treat MS target lymphocytes. However, the factors, in particular HMGB1, that regulate lymphocyte activation during MS are incompletely understood. We have generated a HMGB1 fusion protein to determine the role of HMGB1 on lymphocyte activation in the mouse model of multiple sclerosis, experimental autoimmune encephalomyelitis (EAE). EAE was induced by immunizing C57/BL6 mice with myelin oligodendrocyte glycoprotein $(MOG)_{33-55}$. Mice were injected intraperitoneally with HMGB1 fusion protein before onset of disease. Clinical scores and incidence were determined. MOG specific IgM antibody levels, which is involved in remyelination, was analyzed. IL-17 expression, a pro-inflammatory cytokine linked to EAE pathogenesis was evaluated. HMGB1 fusion protein treated mice exhibit significantly reduced clinical scores during the induction and recovery phases of disease. Reduced severity of disease was associated with a reduced frequency of CD4+T cells in the spinal cord. T cells and B cells were reactive to HMGB1 fusion protein. The CD4+T cell cytokine, IL-17 expression was reduced in the periphery of HMGB1 treated mice. MOG specific IgM antibody titers were significantly elevated compared to the control treatment group. These data indicate that HMGB1 fusion protein attenuates EAE. HMGB1 appears to be involved in regulating inflammation in EAE by negatively influencing CD4+T effector cell functions and positively regulating the maintenance of MOG specific antibody responses. This study reveals new insights into the potential affect of HMGB1 as a therapeutic to reduce inflammation in multiple sclerosis.

Title: *In vivo* effects of β-alanine on some parameters of oxidative stress and enzymes of energy metabolism in cerebral cortex and cerebellum of rats

Authors: *T. GEMELLI, SR[1], R. B. DE ANDRADE[1], D. B. ROJAS[1], N. B. FERNER[1], C. FUNCHAL[2], C. M. D. WANNMACHER[1]
[1]Departament of Biochem. - Federal Univ. of Rio Grande Do Sul, Porto Alegre, Brazil; [2]Ctr. Universitário Metodista, Porto Alegre, Brazil

Abstract: β-alanine is derived from the degradation of uracil. In high concentrations develops a very rare disorder of pyrimidine degradation pathway, known as β-alaninemia. In this study we evaluated the in vivo acute and chonic effects of β-alanine on some parameters of oxidative stress and the activity of the enzymes creatine kinase, pyruvate kinase and adenylate kinase in cerebral cortex and cerebellum of 21-day-old rats. In the acute treatment the animals received three intraperitoneal injections of β-alanine (300 mg /Kg of body weight) and the controls received the same volume of saline solution (0.85%) at 3 hours of intervals. In the chonic treatment the animals received one intraperitoneal injection each 12 hours from 8 to 21 days of age. 2',7'-dihydrodichlorofluorescein (DCFH) oxidation and the content of thiols increased in the two tissues studied. No significant difference in the levels of glutathione (GSH) and thiobarbituric acid reactive species (TBARS) was verified. Catalase (CAT) activity was increased, whereas superoxide dismutase (SOD) activity was inhibited in the two tissues. Considering the enzymes of energy metabolism the results were similar in all enzymes, but different in the two tissues studied: β-alanine was able of inhibit the enzyme pyruvate kinase, cytosolic creatine kinase and adenylate kinase activities in cerebral cortex. However, pyruvate kinase and adenylate kinase activities were increased in the presence of β-amino acid in cerebellum. In the chronic experiment we observed increased content of thiols in the cerebral cortex, whereas no significant difference in the levels of GSH and SOD activity was verified. The activity of the antioxidant enzyme glutathione peroxidase (GPx) and TBARS were reduced. In cerebellum DCFH oxidation was increased whereas the other parameters were decreased. Therefore, the activity of the enzymes of the energy metabolism was different in the two studied tissues. The β-amino acid decreased pyruvate kinase activity and increased cytosolic creatine kinase activity, but did not change adenylate kinase activity in cerebral cortex. However, the pyruvate kinase and adenylate kinase activities decreased in the cerebellum. Finally, we found that β-alanine administration altered the activity of the antioxidant enzymes and increased the content of reactive species possibly generating oxidative stress. The oxidative stress may be a possible cause of the observed alteration in the enzymes of the energy metabolism. Taken

together, these results suggest that oxidative stress and alteration of energy metabolism may contribute, at least in part, to the neurological alterations found in patients with β-alaninemia.

Title: Amyloid precursor protein modulates the nerve transduction in the CNS

Authors: *C. LIU[1], Q. MA[2], S. LI[3], G. DAWE[4], Z. XIAO[5]
[1]Pharmacol., Natl. Universtity of Singapore, Singapore, Singapore; [2]Suzhou Univ., Suzhou, China; [3]Dalian Med. Univ., Dalian, China; [4]Pharmacol., Natl. Universtity of Singapore, Singapore, Singapore; [5]Monash Univ., Melborne, Australia

Abstract: Amyloid precursor protein (APP) is best known for its involvement in the pathogenesis of neurodegenerative disorders, such as Alzheimer's disease, and of other forms of dementia, like Down's syndrome. Although the release of component peptides of APP, including Aβ deposition, has been thought to occur predominantly at synapses, increasing evidence strongly suggests that an important component of AD is damage to axons. APP's physiological distribution and function along axons remain unknown. We report that APP null and APP overexpressing transgenic mice show minor hypo- and hyper-myelination, respectively. The length of node changes in APP KO mice. Interestingly, APP is colocalized with an ion channel in the CNS. Coexpression of APP with the ion channel in Xenopus oocytes resulted in an increase in the peak currents. The cell surface expression of these channels in the white matter of spinal cord is decreased in APP null mice. Consistently, APP deficiency significantly reduces spinal conduction velocity. Thus, APP acts along the axons and modulating the nerve transduction.

Title: Aß Effects on vascular endothelial cells include tip cell formation, migration and lipid peroxidation

Authors: *T. ALKAM, D. W. ETHELL
Mol. Neurobio. Group, Grad. Col. of Biomed. Sciences, Western U, POMONA, CA

Abstract:
Alzheimer’s pathology
includes dense aberrant blood vessel networks between plaques in the brains of affected people and some mouse models of this disease. We recently reported that high physiological levels of monomeric amyloid-beta (Aß1-42) induce angiogenic responses in vitro and in vivo. Here we report on subsequent studies into the mechanisms responsible for angiogenic changes in Human Umbilical Vein Endothelial Cells (HUVEC) that are induced by Aß1-42. An early event in angiogenesis is the transformation of endothelial shaft cells into tip cells, which lead migration away from the shaft to form of new blood vessels. We found that Aß1-42 monomer significantly increased tip cell formation in HUVEC, but the shorter alpha-secretase pathway product, Aß17-42 (monomer), did not. Further, this effect of Aß1-42 could be blocked by several anti-oxidants, including water soluble ascorbic acid, fat-soluble d-alpha-tocopheryl, and a synthetic catalase/superoxide dismutase mimetic EUK207. Cell migration analysis, using a scratch assay, showed that Aß1-42 induced significantly more migration of HUVEC treated with Aß1-42, whereas Aß17-42 did not; and this Aß1-42 migration effect was also blocked by co-treatment with anti-oxidants. Aß1-42 has copper-binding residues and a putative lipid interaction motif that are absent in Aß17-42, so determined if lipid peroxidation correlated with the ability of Aß1-42 to induce migration and tip cell formation. As angiogenesis often requires the production of additional endothelial cells be produced, we have also explored if Aß1-42 and Aß17-42 affect cell cycle progression in HUVEC. Ongoing studies will determine extracellular and intracellular signaling components of that drive these Aß1-42-induced effects on vascular endothelial cell morphology and behavior.

Title: Quantitative analysis and modeling of particle transport in the living axon: Further evidence for a role of amyloid precursor protein in axonal transport.

Authors: *G. ZIOMEK[1], E. BEARER[2], M. LOEWENBERG[3]
[1]Pathology, Univ. of New Mexico Sch. of Med., Albuquerque, NM; [2]Univ. of New Mexico, Albuquerque, NM; [3]Yale, New Haven, CT

Abstract: Several different cargo-motor receptors for transport have been proposed based on their in vitro binding affinities to kinesin-1. One of these, a 15-amino acid domains from the carboxyl terminus of amyloid precursor protein has been reported to mediate motility in living systems. Here we describe an experimental assay for identification of cargo-motor receptors by their ability to drive transport of exogenous cargo in the axon. Cargo is engineered by derivatizing the surface of polystyrene fluorescent nanospheres with charged residues or with synthetic peptides derived from candidate motor receptor proteins, all designed to display a terminal COOH group. After injection into the squid giant axon, particle movements are imaged by laser-scanning confocal time-lapse microscopy. In this report, new control beads and a strategy to quantitate frequency of bead movements are evolved beyond our previous reports. The ensuing quantitative analysis of time-lapse digital sequences reveals detailed information about bead movements: instantaneous velocity, run lengths, pause frequencies and pause durations. These measurements are then used to provide parameters for a mathematical model that predicts the spatiotemporal evolution of distribution of bead cargo in the axon. The results reveal the dynamics of active intracellular transport of cargo displaying a single species of motor receptor on its surface. The significance of this data and accompanying model pertains to the role transport plays in neuronal function, connectivity, and survival, and has implications in the pathogenesis of neurological disorders such as Alzheimer’s, Huntington and Parkinson’s diseases. Title: mTOR pathway characterization in AD brain and a Cellular Model.

Authors: *H.-K. LEE, B. KWON, H. W. QUERFURTH
Neurol., Rhode Island Hosp. and Brown Univ. Warren Alpert Med. Sch., Providence, RI

Abstract: ___The mTOR pathway is a central controller of cell growth, proliferation and physiological processes such as protein biogenesis and autophagy. The mTOR is recently involved in maintaining glucose homeostasis. Activation of mTOR and downstream signaling is inhibited in some animal and cellular models of AD whereas it is up-regulated in others. Moreover, the mTOR complex is in turn partially regulated by Akt which has additional trophic actions on mitochondrial function and synaptic plasticity. Interference with the Insulin/PI3K/Akt signaling pathway has emerged as another important aspect of AD, however there is again disagreement between groups using various models on the direction of change.
___We used a cellular model of AD characterized by accumulation of beta-Amyloid42 in cultured neurons and compared results to brain tissue from AD patients. Levels of total and phospho-mTOR were determined by Western in native N2a and SHSY5Y cultures and after experimental expression of beta-amyloid1-42.
___mTOR inhibition showed partial blockage of intracellular beta-Amyloid induced toxicity. Inhibition of Akt and CREB under beta-amyloid expression conditions was accompanied by an increase in p-mTOR/tot-mTOR ratio and in p-4EBP1. This paradoxical shift and the Akt change were both also reversed by rapamycin. The added role of insulin resistance, while appearing to follow and exacerbate the amyloid effect, is being examined in molecular detail. Inhibition of mTORC1 and activation of mTORC2 may rescue both amyloid and non-amyloid mechanisms of insulin resistance.

Title: Systems Biology of β - amyloid peptide in Alzheimer's disease

Authors: *J. BALI[1,2], B. SIEGENTHALER[1,2], C. TACKENBERG[1], G. THAKUR[1,2], S. ZURBRIGGEN[1,2], L. RAJENDRAN[1,2]
[1]Univ. Of Zurich, Zurich, Switzerland; [2]Systems and Cell Biol. of Neurodegeneration, Div. of Psychiatry Res., Univ. of Zurich, Zurich, Switzerland

Abstract: β- Amyloid (Aβ) peptide, causally linked to neurodegeneration in AD is produced by sequential processing of amyloid precursor protein (APP) by the β-and γ-secretases. While the production of Aβ requires only 3 core components, namely, APP, β and γ secretase, its production at the cellular and organismal context is a complex process due to the interplay of many genes, proteins and signaling networks. To elucidate the cellular signaling mechanisms that regulate the production of Aβ peptide we used gene silencing strategies using small interfering RNAs (siRNA) and performed genome wide screen of all kinases. To analyze the effect of knock down on APP processing, we developed a multiplexing high-throughput screening platform to assay levels of Aβ and sAPPβ (the two products of amyloidogenic processing of APP) within the same well of a 384 well plate. Based on Aβ, sAPPβ values we divided the hits into two groups, those regulating APP and/or β-secretase, (affecting Aβ and sAPPβ) and those regulating γ-secretase, (affecting only Aβ). We identified a large set of kinases as regulators of APP processing. We also found that APP processing is regulated by signaling networks, including Wnt signaling, chemokine receptor signaling and the MAPK pathway. This work reveals the importance of signaling networks and pathways in Aβ metabolism and the utility of functional genomics in understanding the complexity of neurodegenerative diseases.

Title: Insulin signaling affects the levels of cholesterol and Aβ production in neuroblastoma 2a cells

Authors: *D. NAJEM[1], W. ZHANG[2,3]
[1]CMM, [2]Fac. of Med., Univ. of Ottawa, Ottawa, ON, Canada; [3]Natl. Res. Council of Canada, Ottawa, ON, Canada

Abstract: One of the neuro-pathological hallmarks of Alzheimer's disease (AD) is the accumulation and deposition of β-amyloid peptides (Aβ) in brain parenchyma and cerebral vessels. These peptides form oligomers and senile plaques, evoke neuroinflammation, and have been implicated in insulin signaling disruption. Also, higher levels of cholesterol are reported in AD pointing to dysergulation of cholesterol homeostasis. In this study, we hypothesize that dysregulation of insulin signaling in AD may affect the expression of the enzymes involved in cholesterol regulation/synthesis leading to alteration of cholesterol metabolism, secretase activities, APP processing and Aβ production in neural cells. To test whether insulin treatment affects cholesterol levels, cholesterol synthesis enzymes, and Aβ production, mouse neuroblastoma 2a cells transfected with human APP gene (N2a-APP) were treated with 10µg/ml insulin for 2, 6 and 12 hours. Cholesterol levels are measured in the cytosolic fraction of the cells and Aβ1-40 and Aβ1-42 levels are measured by ELISA in the medium. Western blot confirms Akt signaling was activated in cells. The cholesterol levels decreased at 2 and 6 hours and increased at 12 hours in parental neuroblastoma 2a cells with similar trends observed for N2a-APP cells. The levels of Aβ1-40 decreased at 2 and 6 hours in N2a-APP cells with similar decreasing trends for Aβ1-42 levels. Protein levels of cholesterol regulatory enzymes were investigated, including 3-hydroxy-3-methylglutaryl-CoA reductase (HMGCR), and 7-dehydrocholesterol reductase (DHCR-7). There is a trend of decreased levels of both proteins at 6 and 12 hours, an increased level of HMGCR-7 at 2 hours and a trend of decreased levels of DHCR7 at 2 hours for both cell lines mimicking the results obtained in the cholesterol assay. Furthermore, there may be a redistribution of cytosolic cholesterol to the membranes at earlier time points accounting for the observed cytosolic level decrease. The trend of decrease of Aβ may be due to increased expression of insulin degrading enzyme in response to increased insulin

levels observed by western blotting at 2 and 6 hours in N2a-APP cells. Further experiments are underway to evaluate cholesterol distribution using a cell-base detection assay and fractionation assay. Future experiments will investigate mRNA levels of tested proteins by QPCR, α,/β,/γ-secretase activities by activity assays, and cholesterol levels will be measured in brains extracted from IDE/LDLr-KO mice. In conclusion, activation of insulin signaling seems to have significant effects on Akt activation, cholesterol homeostasis and Aβ metabolism in neural N2a and N2a-APP cells.

Title: Synaptic homeostatic changes alter the expression and localization of amyloid precursor protein

Authors: *C. DELBOVE, R. M. LAZARENKO, X. GAO, B. EDBERG, Z. QI
Pharmacol., Vanderbilt Univ., Nashville, TN

Abstract: Recent clinical data suggest that chronic change of synaptic activity is associated with the generation of soluble oligomers of beta-amyloid (A beta) and likely amyloid plaque deposition. As the production of A beta aggregates involves amyloid precursor protein (APP) expression, APP proteolysis, and A beta cleansing, the mechanism underlying homeostasis-induced amyloid development remains unknown. We are investigating this by examining the expression, distribution and processing of most APP isoforms found in the central nervous system. Using reverse transcription quantitative PCR, we found that the neuronal and glial APP variants exhibited different expression levels upon chronic elevation or suppression of synaptic activity over time. Using western blot and immunocytochemistry, we investigated the changes in APP distribution in the plasma membrane or cytosolic lipid compartments in different parts of various types of neurons. Using APP knockout and overexpression mice, we were able to

decouple APP expression and synaptic homeostasis. We found that consistently higher or lower levels of APP feed back to the homeostatic changes, especially affecting presynaptic terminals. Therefore, we concluded that APP is an indispensible regulator of synaptic homeostasis and abnormal synaptic activity can lead to pathological accumulation of APP and A beta.

Title: The effect of the activation/inhibition of the canonical Wnt Pathway on APP processing

Authors: C. PARR, N. MIRZAEI, *M. SASTRE
Imperial Col. London, London, United Kingdom

Abstract: Alterations in the Wnt signalling pathway may play an important role in the pathogenesis of Alzheimer’s disease (AD) because of its effects on axonal growth, on synaptogenesis and amyloid-β (Aβ) toxicity. Activation of the canonical Wnt pathway depends on inhibition of GSK3, leading to decreased phosphorylation of β-catenin, preventing its proteasomal degradation and allowing it to enter the nucleus to regulate gene transcription by complexing with TEF/LCF transcription factors. In this study we sought to determine whether activation or inhibition of the canonical Wnt pathway affected the processing of the amyloid precursor protein (APP). We have previously shown that GSK3 inhibition affects Aβ generation (Parr et al., 2012). To evaluate Wnt activation, we transfected N2a cells with either Wnt3a or β-catenin S33 (a mutant that cannot be degraded in the proteasome). On the other hand, the Wnt pathway was inhibited by transient transfection of N2a cells with two known antagonists, sFRP-1 and DKK-1. sFRP-1 inhibits the pathway by antagonizing the Wnt/Fz binding. DKK-1 inhibits the canonical Wnt pathway by binding to LRP6, the Wnt co-receptor. Activation of the canonical Wnt pathway resulted in a decrease in Aβ levels and in β-carboxy terminus fragments (CTFs). In addition, transient transfection of Wnt3a and β-catenin S33 reduced the transcription, expression and activity of BACE1. Conversely, inhibition of the Wnt pathway increased Aβ generation and elevated the amyloidogenic processing of APP. Consistent with these results, inhibition of the pathway was also found to increase the transcription, expression and activity of BACE1. In conclusion, the canonical Wnt signalling pathway seems to be involved in the regulation of

BACE1 transcription and consequently in the generation of Aβ. The specific mechanisms of this transcriptional control remain to be elucidated.

Title: Calsyntenin-1 vesicles shelter APP from proteolytic processing during anterograde axonal transport

Authors: *T.-M. DIEP[1], M. STEUBLE[1], P. SCHÄTZLE[1], A. LUDWIG[1], M. TAGAYA[2], P. SONDEREGGER[1]

Abstract: Endocytosis of amyloid-β precursor protein (APP) is thought to represent the major source of substrate for the production of the amyloidogenic Aβ peptide by the β-secretase BACE1. The irreversible nature of proteolytic cleavage implies the existence of an efficient replenishment route for APP from its sites of synthesis to the cell surface. We recently found that APP exits the trans-Golgi network in intimate association with calsyntenin-1, a transmembrane cargo-docking protein for Kinesin-1-mediated vesicular transport. Here we used selective immunoisolation and biochemical characterization of organelles of the intracellular trafficking routes, immunocytochemistry and live-imaging of intracellular trafficking organelles, and RNAi to characterize the function of calsyntenin-1 in neuronal APP transport. We found that APP is co-transported with calsyntenin-1 along axons to the early endosomes in the central region of growth cones in a carrier that excludes the α-secretase ADAM10. Intriguingly, the calsyntenin-1/APP organelles contained BACE1, suggesting premature cleavage of APP along its anterograde path. However, we found that APP contained in calsyntenin-1/APP organelles was stable. We further analyzed vesicular trafficking of APP in cultured hippocampal neurons, in which calsyntenin-1 was reduced by RNAi. We found hitchhiking of APP with other anterograde

carriers, such as ADAM10-containing vesicles of the secretory pathway. Increased proteolytic processing of APP and Aβ secretion in these neurons suggested that the reduced capacity for calsyntenin-1-dependent APP transport resulted in the premature encounter of unprotected APP with its ectodomain proteases. In combination, our results characterize calsyntenin-1/APP organelles as a carrier for sheltered anterograde axonal transport of APP.

Title: Exploration of epigenetic small molecule modulators of β-amyloid production

Authors: *H. SALAH-UDDIN, C.-H. VOLMAR, P. HALLEY, C. WAHLESTEDT
Ctr. for Therapeut. Innovation and Dept. of Psychiatry and Behavioral Sc, Univ. of Miami - Miller Sch. of Med., Miami, FL

Abstract: Alzheimer’s disease (AD) is the leading cause of senile dementia with approximately 5.4 million people afflicted with the disease in the USA alone (Alzheimer’s disease facts and figures, 2012). The amyloid cascade hypothesis links amyloid beta (Aβ) to the pathophysiology of AD, triggering plaque formation, tau hyperphosphorylation, neurodegeneration and eventually death. Aβ is the product of the sequential proteolytic cleavage of the amyloid precursor protein (APP) by the proteases β- and γ-secretases. Emerging research suggests that epigenetics may play a role in the etiology of late onset AD (LOAD), the most common form of the disease. Indeed, abnormal changes in DNA methylation and/or acetylation have been observed in AD cases and in vitro. Targeting both histone deacetylases (HDAC) and histone acetyltransferases (HAT) have thus been proposed as potential therapies against AD and small molecules that effect epigenetic targets have been shown to attenuate Aβ accumulation in AD models. In this study, we have confirmed anti-amyloidogenic effect of trichostatin A and resveratrol, in vitro. We have also identified other small molecules with possible epigenetic mechanism(s) of action that cause greater reduction of Aβ1-40 and Aβ1-42 levels. Work is under way to further decipher the mode of action of these molecules on APP and its processing. This study supports the hypothesis that targeting epigenetics pathways with small molecules may be a suitable therapeutic approach against AD.

Abstract: Research on Alzheimer’s disease (AD) has been hampered by lack of appropriate models to recapitulate the human nervous system. Advances in stem cell technology make it possible to generate human neurons harboring the mutations that are strongly associated with specific neurodegenerative diseases. Amyloid-β peptide (Aβ) is the key pathogenic molecule in AD. Mutations in amyloid β precursor protein (APP) and presenilin (PS) are strongly associated with early-onset AD by increasing toxic Aβ. Here, we developed human neural progenitor cells (hNPCs) genetically modified to over-produce Aβ. For these studies, we used an immortalized human neural progenitor cell line derived from the fetal brain. Lentiviral constructs were generated to overexpress AD genes, including APP with K670N/M671L and V717I familial AD (FAD) mutations (APPSL), PS1, PS1 with deltaE9 FAD mutation (PS1dE9), and BACE1. We established hNPC lines stably expressing APPSL, PS1, PS1dE9, or BACE1. hNPCs co-expressing APPSL/ PS1dE9 or APPSL/PS1dE9/BACE1 were also generated to produce more toxic Aβ species. The hNPCs were then differentiated into neuronal and glial cells under growth factor free media for 30-40 days and the expression of the transfected AD genes were confirmed by Western Blot analysis. We also measured secreted Aβ40 and 42 levels by ELISA. As expected, the hNPCs with APPSL, APPSL/PS1dE9, and APPSL/PS1dE9/BACE1 showed dramatic increases in Aβ40 (up to 12 fold) and Aβ42 (up to 13 fold) levels compared to control hNPCs. Remarkably, coexpression of APPSL and PS1dE9 increased the Aβ42/40 ratio by 5 fold, confirming a pathogenic role of PS1dE9 mutation. As a proof-of-concept experiment for future AD drug screening, we treated the APPSL cells with an experimental γ-secretase modulator and

found that this modulator significantly decreased both total Aβ levels and the Aβ42/40 ratios. Taken together, our data strongly support that the genetically modified hNPCs can serve as a rapid and robust AD models for basic research and drug screening.

Title: Neutrophin trafficking deficts are mediated by impaired ubiquitin recycling in AD

Authors: B. L. AGUILAR, *W. W. POON, A. J. CARLOS, C. W. COTMAN
UC-Irvine, IRVINE, CA

Abstract: Utilizing a novel microfluidic culture chamber, we demonstrate that neurotrophin-mediated retrograde signaling deficits caused by Aβ is mimicked by LDN, an inhibitor of Ubiquitin-C-terminal hydrolase L1 (UCH-L1), a deubiquitinating enzyme that functions to maintain cellular ubiquitin homeostasis. We demonstrate that Aβ impairs Trk receptor internalization and retrograde signaling endosome trafficking, including p-ERK5 signaling and CREB-dependent gene expression. We also show that some of these deficits can be reversed by increasing cellular UCH-L1 levels. Our results suggest that a consequence of the impaired proteasome function is defective regulation of ubiquitin homeostasis leading to impaired Trk-mediated retrograde signaling compromising neuronal survival.

Title: Cross-linking of cell surface APP leads to increased Aβ production in hippocampal neurons - Implications for Alzheimer's disease

Authors: *R. LEFORT, J. POZUETA, M. SHELANSKI
Columbia Univ., New York, NY

Abstract: The accumulation of the β-amyloid peptide (Aβ) in Alzheimer's disease (AD) is thought to play a causative role in triggering synaptic dysfunction in neurons leading to their eventual demise through apoptosis. Aβ is produced and secreted upon sequential cleavage of the amyloid precursor protein (APP) by β- and γ-secretases. However, while Aβ levels have been shown to be increased in AD patients' brains, little is known about how the cleavage of APP and the subsequent generation of Aβ is influenced, or if the cleavage process changes over time. It has been proposed that Aβ can bind APP and promote amyloidogenic processing of APP, further enhancing Aβ production. This idea has remained controversial due to a lack of a clear mechanism and complicated by the promiscuous nature of Aβ binding. To work around this problem, we used an antibody-mediated approach to bind and cross-link cell surface APP in cultured rat primary hippocampal neurons. Here we show that cross-linking of APP is sufficient to trigger a loss of dendritic spines in neurons, while simultaneously increasing the levels of Aβ in viable neurons. We further demonstrate that this involves two independent mechanisms, with caspase-2 mediating the synaptic effects and caspase-3 regulating the increase in Aβ production. More specifically, cross-linking of APP triggers the activation of caspase-2, followed by the activation RhoA, leading dendritic spine collapse. Cross-linking of APP also activates caspase-3 which inactivates the adaptor protein GGA3, leading to the accumulation of BACE1 and Aβ. Taken together, our data suggest the occurrence of a positive pathogenic feedback loop involving Aβ and APP in affected neurons possibly allowing Aβ to spread to nearby healthy neurons.

Title: The effect of zinc on the dimerization, processing, and trafficking of amyloid precursor protein

Authors: *W.-W. CHANG, Y.-R. CHEN
Genomics Res. Center, Academia Sinica, Taipei, Taiwan

Abstract: Alzheimer's disease (AD) is the most prevalent, age-related neurodegenerative disease that accounts for > 50% of the dementia cases. The presence of extracellular β-amyloid (Aβ) in the brain is one of the classic characteristics of AD besides the intracellular neurofibrillary tangles. In post-mortem AD brains, zinc is significantly increased within Aβ plaques which renders zinc an important player in AD etiology. Moreover, zinc has been shown to accelerate Aβ deposition. Aβ is a cleaved peptide fragment of amyloid precursor protein (APP) that is a type I transmembrane protein with a large ectodomain (contains two major regions, E1 and E2), a single transmembrane region, and a short intracellular region. APP can form dimers in which three regions have been reported to promote its dimerization. They are the E1 domain, E2 domain ,and the G*XXX*G motif near the luminal face of the transmembrane region. APP dimerization is able to modulate APP processing and Aβ production. Since APP contains zinc binding motifs in its amino-terminal domain and Aβ region and previous study has shown that zinc can induce dimerization of $APP^{170-188}$ peptide without knowing the effect on full-length APP, we would like to elucidate the mechanism of zinc effect toward APP dimerization, processing, and trafficking using cellular assays. In this study, by the strategy of bimolecular fluorescence complementation and chemical cross-linking, we demonstrated that zinc indeed induced APP dimerization in human kidney cells, HEK293T and human neuroblastoma, SH-SY5Y cells. Besides, zinc enhanced Aβ production that is likely resulting from APP dimerization. Further, we investigated the zinc binding motifs and observed the effect on APP trafficking. Overall, our results help to elucidate the roles of APP and zinc in AD pathogenesis and facilitate the development of future therapeutic strategies.

Title: Influence of ganglioside biosynthesis in Alzheimer's amyloid precursor protein (APP)-expressing cells

Authors: *T.-W. LIN, Y.-R. CHEN
Genomics Res. Center, Academia Sinica, Taiwan, Taipei, Taiwan

Abstract: Alzheimer's disease (AD) is the most common dementia in the elderly. Dementia describes significant loss of certain mental functions such as memory, attention, and abstract thinking. The primary neuropathologic hallmark in AD is senileamyloid plaques comprising of amyloid fibrils. Plaque formation is believed to result from increased production or decreased clearance of the amyloid-β beta (Aβ) peptide, which is generated fromby subsequent, proteolytic cleavages of a type I membrane protein larger precursor protein known as amyloid precursor protein (APP) via β- and γ-secretases. Several strong indications point towards an important role of gangliosides in AD pathogenesis. Gangliosides are sialic acid-containing glycosphingolipids (GSLs) that are expressed in the outer leaflet of the plasma membrane of all vertebrate cells and enriched in the central nervous system. Gangliosides play are involved important roles in a variety of cellular functions, including serving as antigens, receptors for bacterial toxins, mediators of cell adhesion, and mediators/modulators of signal transduction. In this study, we have generatedcreated stable cell lines for different APP isoforms stable lines including APP770, APP751, APP695 in human neuroblastoma SH-SY5Y and human embryonic kidney cells HEK293T cells. By using flowcytometry analysis, Wwe found ganglioside contents were much more abundant in SH-SY5Y than HEK293T. In addition, we observed decrease of GD3 and GD1a in all overexpressed APP770/751/695 HEK293T stable lines. However, the changes of other gangliosides examined (including GM1, GM2, GD3, GD2 and GD1a) levels awere presented differently in APP isoformisoform expressing SH-SY5Y stablecell lines. Furthermore, we used thin layer chromotagraphychromatography (TLC) to confirm thise result and used reverse transcription to detect different expressing levels of the glycotransferase levels. Our results Through the cell surface ganglioside examination, we suggest molecular mechanisms for the changes of gangliosides biosynthesis in AD.

Title: Mitochondrial dysfunction in a human neuronal cell model of early Alzheimer`s disease

Authors: *C. SCHILLER[1], K. LEUNER[2], W. E. MUELLER[1]
[1]Pharmakologie für Naturwissenschaftler, Goethe Univ. Frankfurt, Frankfurt Am Main, Germany; [2]Dept. of Mol. and Clin. Pharm., Univ. of Erlangen, Erlangen, Germany

Abstract: The important role of mitochondrial dysfunction in Alzheimer's disease (AD) is widely acknowledged. Besides brain aging, mitochondrial dysfunction is a consequence of high amyloid beta (Aß) and hyperphosphorylated tau levels, two major histopathological hallmarks of AD.
In previous studies we were able to show that HEK and PC12 cells, which are stably transfected with DNA constructs for wildtype human amyloid precursor gene (APPwt) exhibit mitochondrial dysfunction compared to the corresponding vector cells (Co). Because human embryonic kidney cells are a peripheral cell line and phaeochromocytoma cells12 are neuronal, but originate from the rat, we now focus on SY5Y cells as a human neuronal cell line. When transfected again with the same construct, these cells have Aß levels approximately 1.5 fold higher than the control levels. Thus, SY5Y-APPwt cells represent an appropriate human cell model for the early stages of AD.
In order to investigate mitochondrial function of the transfected cells relative to vector controls, we measured ATP levels, mitochondrial membrane potential, and mitochondrial length. Both ATP and mitochondrial membrane potential are significantly reduced in APPwt cells underlying the assumption of mitochondrial dysfunction representing a very early event in the development of AD. Using confocal microscopy analysis, we were also able to demonstrate that the mitochondrial morphology is clearly different between the two cell types. In comparison to APPwt cells control cells possess much more tubular and elongated mitochondria, suggesting that already low Aß levels lead to enhanced fragmentation.
To further characterize the neuronal function of these human neuroblastoma cells we have determined neurite outgrowth in both cell types in the presence of BDNF. Interestingly, APPwt cells show significantly longer neurites under basal conditions, indicating that very low Aß levels can lead to a compensatory increase of neurite outgrowth, at least in the beginning.
In summary, our findings highlight the impairment of mitochondrial function as consequence of only slightly elevated amyloid beta levels as well as a compensatory improvement of other parameters.

Title: Epicatechin inhibits beta-secretase mediated APP processing and reduces amyloid beta pathology in APP/PS1 transgenic mice

Authors: *C. J. COX[1], F. CHOUDHRY[2], D. R. HOWLETT[2], P. T. FRANCIS[2], R. J. WILLIAMS[1]
[1]Biol. and Biochem., Univ. of Bath, Bath, United Kingdom; [2]Wolfson Ctr. for Age-Related Dis., King's Col. London, London, United Kingdom

Abstract: Mounting epidemiological evidence suggests that a flavonoid-rich diet can inhibit the development of dementia (Williams and Spencer, 2012). In relation to Alzheimer's Disease (AD) some flavonoid-rich extracts have been shown to exert beneficial effects on amyloid beta (Aβ) pathology, although the mechanism remains uncertain. The aim of this study was to identify single, isolated flavonoid compounds that were able to modulate Aβ pathology at physiologically relevant concentrations. Development of a cell-based reporter gene luciferase assay in primary neurons has enabled βγ-secretase-mediated APP processing to be studied in cells with functional synapses. Primary cultured embryonic mouse cortical neurons (5 DIV) were transfected with APP_{695}Gal4, pFR-luciferase and TK-Renilla, with or without Fe65, using lipofectamine 2K and activity assessed by luminescence. Basal luciferase expression was potentiated 10 fold following co-transfection with the adaptor protein Fe65. Mutagenesis of APP_{695}Gal4 to generate the Swedish mutant (KM/NL) APP_{695}SweGal4 caused a 2 fold increase in expression demonstrating sensitivity to pathological conditions. Transfected neurons were treated with select flavonoids (100nM and 10 μM, 24 h) to identify novel secretase modulators. Epigallocatechin (EGC) and (-)-epicatechin (EC) were taken forward as lead compounds and showed potent inhibition of luciferase expression with IC50s of 18.6 nM and 20.5 nM respectively. Despite similar potencies, the kinetics of inhibition differed; EGC was effective at 24h whilst EC was effective at 6h. Due to the established bioavailability of EC it was selected for administration to APP/PS1 mice via drinking water (10mg /day) for 21 days and Aβ pathology assessed. EC supplemented mice showed decreased Aβ plaque density and evidence of reduced soluble Aβ in cortex. Collectively this study supports the development of EC and other proanthocyanidins (Wang et al., 2012) for therapeutic use in AD.

Title: DNA-damage response as a possible mechanism underlying common pathways involved in the effects of beta-amiloid overexpression, distress, and cancer.

Authors: *S. ORTEGA MARTINEZ[1], J. SERRANO[1], A.-P. FERNÁNDEZ[1], S. GONZALO[2], R. MARTÍNEZ-MURILLO[1], J.-L. TREJO[1]
[1]Inst. Cajal, Madrid, Spain; [2]St. Louis Univ., St.Louis, MO

Abstract: Objective: We have addressed the putative interaction between beta-amyloid overexpression and cancer signalling in brain stem cells focused on the DNA-damage response, both in basal conditions and after administration of stress hormones.
Materials and methods: For this goal we used 3 astrocytomas cells lines [CT2A (control), APP-PS1 L.1 and APP-PS1 L.3 (cell lines of astrocytoma obtained from mice APP/PS1)] and both neural stem cells from the brain of control mices and neural stem cells from the brain of APP-PS1 mices.
To cause DNA damage, cells were irradiated with 5 Gray (Gy) for all experiments. We evaluated this DNA damage by immunofluorescence p53 binding protein 1 (53BP1) foci as indicator of Non Homologous End-Joining (NHEJ) pathway and γH2AX foci as indicator of double strand breaks (DSBs). To set DNA repair kinetic we based on Neutral comet assay.
Results: We have found that APP/PS1 cell lines studied show a basal DNA damage weighed up by the presence of γ-H2AX, and these cells show a marker corresponding by oxidative DNA damage [8-hydroxy-2′-deoxyguanosine (8OHdG)], which is also present in neural stem cells from the brain of APP/PS1 mice.
It worths to take into account the results obtained after administration of dexamethasone (50μM)

on the different cell lines. The response consisted of an exacerbation of the DNA-damage signalling and repair compared to the controls treated with vehicle, especially at the longer time periods analyzed, although no differences were found between cell lines. Furthermore studies realized by Neutral comet assay show that all astrocytomas cell lines impair non-homologous end joining pathway when we treated with dexamethasone before irradiation. Interestingly, this result is completely different when assayed in neural stem cells from normal brains, where preincubation with dexamethasone before irradiation decreased number of cells displaying foci. On the other hand, neural stem cells from APP-PS1 brain show a different signal. Basal DNA damage is the most important characteristic in this cells which have the highest level found corresponding with γ-H2AX foci, but dexamethasone treatment decrease levels of positive cells foci when cells are not irradiated.
Conclusion: The deleterious effects of beta-amyloid overexpression and the cancer signalling can result additive when appear together in the same cell, at least as observed for the DNA-damage response and repair system. Similarly, the different responses of DNA-damage to high levels of stress hormones may also depend on the distinct combination of beta-amyloid expression level and cancer signalling, as demonstrated by the different effects in the distinct cell lineage.

Title: Spatial memory facilitation by electrical stimulation of the medial septum in rats

Authors: *D. JEONG[1], J. LEE[1], S. LEE[2], S. KIM[2], J. CHANG[1]
[1]Brain Korea 21 Project Med. Sci.&Yonsei Univ. Coll. of Med., Yonsei Univ. Coll. of Med., Seoul, Korea, Republic of; [2]Sch. of Electrical Engin. and Computer Science, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Recently, deep brain stimulation has been used to treat various neurological disorders. Some studies support that DBS can be a strategy to treat Alzheimer’s disease. The aim of this

study was to evaluate the effect of electrical stimulation in the medial septum using rat model mimicking basal forebrain cholinergic deficits of Alzheimer's disease.
Four experimental groups were composed of normal, lesion, lesion + implantation and lesion + stimulation. 192 IgG-saporin (Selective cholinergic toxin, 8ul of 0.63ug/ul) were bilaterally injected into the lateral ventricle. Electrode was stereotactically implanted into the left medial septum (AP +0.6, ML 0.16, DV -6). Stimulation parameters are 50Hz, 120us pulse width and 1 volt. One week after implantation, Stimulation started for 2 weeks. Two weeks after surgery, water maze was performed for 1 week and rats were sacrificed immediately after behavioral test. Features were verified by immunochemistry and AChE assay.
During the training trials, latencies of lesion and implantation significantly increased in day3 and day4. In contrast, latency of stimulation group had no differences as compared to normal group but it decreased significantly when compared to lesion group in day4. In the probe test, lesion group had decreases in time in target quadrant, time in platform zone and the number of platform crossing. Although they did not perform as normal group, stimulation group showed tendency of recovery. IHC and AChE assay are ongoing.
Spatial memory is associated with hippocampus. We had expected activation of hippocampus by stimulation of the medial septum. We confirmed that stimulation of the medial septum facilitates acquisition and recall of spatial memory. Currently we are studying the effects of medial septal stimulation on the hippocampus.

Title: Group II mGluR antagonist reduces brain Aβ, stimulates hippocampal neurogenesis, and reverses transgene-induced behavioral deficits in APP E693Q transgenic mice

Authors: *S. KIM[1,2], J. W. STEELE[1,2,3], S. W. LEE[6], D. CLEMENSON[6], C. GLABE[7], M. E. EHRLICH[1,4], F. H. GAGE[6], S. GANDY[1,2,5,8]

Studies, La Jolla, CA; [7]Mol. Biol. and Biochem., Univ. of California, Irvine, Irvine, CA; [8]James J Peters VA Med. Ctr., Bronx, NY

Abstract: A key event in the pathogenesis of Alzheimer's disease (AD) is accumulation of neurotoxic amyloid beta (Aβ) oligomers in the brain, formation of which is dependent on the concentration of monomeric Aβ42 peptides. We reported that activation of Group II metabotropic glutamate receptors (Gp II mGluR: mGluR 2, mGluR3) triggers Aβ42 production at the synapse in vitro, which is selectively suppressed by antagonist pretreatment (Kim et al., J Neurosci, 2010). We thus hypothesized that chronic suppression of Gp II mGluR signaling might slow disease progression by reducing the accumulation of Aβ oligomers. Notably, Gp II mGluR antagonists stimulate hippocampal neurogenesis, enhance cognition, and provide antidepressant-like/anxiolytic effects in wildtype rodents. Combined with the synaptic Aβ42-reducing activity, Gp II mGluR antagonists appear to possess a number of properties that might be useful in the prevention or treatment of AD. Pilot studies were performed in "oligomer-only" mice (APP E693Q; Gandy et al., Ann Neurol, 2010) and wildtype littermates (7-10 months old), both of which were treated with either BCI-838 (oral prodrug of BCI-632, a Gp II mGluR antagonist, 5 mg/kg p.o.) or vehicle for 3 months. Reduction in anxiety was observed in BCI-838 treated oligomer-only mice in the elevated plus maze. Chronic administration of BCI-838 corrected transgene-induced learning and memory deficits in oligomer-only mice in both contextual fear conditioning and novel object recognition tasks. Chronic inhibition of Gp II mGluR activity reduced the levels of prefibrillar oligomeric Aβ in the cortex and Aβ42 levels in the hippocampi of APP E693Q mice when compared to vehicle-treated APP E693Q mice. Notably, chronic BCI-838 treatment stimulated hippocampal progenitor cell proliferation, which resulted in a significantly increased number of surviving newborn neurons in APP E693Q mice. We propose that Gp II mGluR antagonists are promising compounds for the prevention or treatment of AD because of their unique combination of synaptic Aβ42- and Aβ oligomer-lowering activity combined with pro-cognitive, antidepressant, anxiolytic, and pro-neurogenic activities. Title: A novel drug candidate for Alzheimer’s disease increases the number of functional synapses in the CA1 region of the hippocampus, in the absence of enhanced LTP

Authors: *A. L. MEGILL[1], A. KIRKWOOD[1], H.-S. HOE[2], H.-K. LEE[1]
[1]Johns Hopkins Univ., Baltimore, MD; [2]Georgetown Univ., Washington D.C., DC

Abstract: Alzheimer's disease (AD) is a neurodegenerative disease characterized by a loss of synaptic contacts in both the neocortex and hippocampus, causing a decrease in synaptic transmission and cognitive decline. While AD is usually characterized by accumulation of amyloid plaques (comprised of aggregated Aβ peptides), loss or alteration of dendritic spines might be one of the first signs of AD pathology, preceding plaque deposition. An ethylene glycol derivative of the benzothiazole aniline (BTA) class of compounds, BTA-EG4, is a novel drug candidate for AD, which was identified by its ability to bind Aβ. Current therapies in AD are symptomatic only, but BTA-EG4 may be able to prevent the progression of AD pathology by potentially decreasing pathologic functions of Aβ. Our collaborators at Georgetown University found that BTA-EG4 decreases Aβ production, increases the density of dendritic spines in CA1, and improves spatial learning and memory. Here we examined whether the structural and behavioral changes are associated with functional changes at synapses. To do this, we measured synaptic transmission and plasticity in the CA1 region of the hippocampus after low (15 mg/kg) and high (30 mg/kg) dose injections of BTA-EG4 in C57BL/6 mice. We found that BTA-EG4 increases the frequency of AMPA receptor-mediated miniature excitatory postsynaptic currents (mEPSCs), which suggests that the increased spine density reflects increases in the number of functional excitatory synapses. However, there was no change in the amplitude of mEPSCs suggesting that the drug does not alter the strength of individual synapses. In addition, there was no change in the input-output function of synapses following BTA- EG4 treatment, which suggests normal basal synaptic transmission. Furthermore, we did not observe an increase in the magnitude of LTP induced at the Schaffer collateral (SC) input nor at the temporo-ammonic (TA) input to CA1. To the contrary, there was a significant reduction in the magnitude of LTP with certain induction protocols. This suggests that the improved learning and memory is not due to enhancement of LTP at synapses. Interestingly, BTA-EG4 decreased the summation of

synaptic responses during all LTP induction protocols suggesting that there may be enhancement of downstream signaling to sustain LTP. Indeed, our collaborators observed that BTA-EG4 increased Ras activity, which is necessary for its ability to increase dendritic spine density. Collectively, our results suggest that BTA-EG4 may benefit cognitive function by increasing the number of functional synapses, which may provide a larger capacity to store information, in the absence of enhanced LTP.

Title: PPARγ agonism promotes the formation of a nuclear hippocampal pERK-PPARγ complex during the memory consolidation phase that mediates cognitive rescue in Tg2576 Alzheimer's mice

Authors: *J. B. JAHRLING[1], L. DENNER[2], K. T. DINELEY[3]
[1]Neurosci., [2]Intrnl. Med., [3]Neurol., Univ. of Texas Med. Br., Galveston, TX

Abstract: The hippocampus is requisite for the establishment and storage of new memories and is particularly vulnerable to the ravages of Alzheimer's disease (AD). Recent clinical trials suggest that treatment of early-AD patients with drugs that activate PPARγ can improve hippocampus-dependent cognitive function. PPARγ agonism via the selective agonist rosiglitazone (RTZ) rescues hippocampus-dependent cognitive deficits in the Tg2576 AD mouse model. Using qPCR and quantitative mass spectrometry, we found that RTZ-mediated cognitive rescue is accompanied by the induction of several PPRE-containing genes and PPARγ-regulated proteins, many of which are important for mitochondrial and synaptic function including components of the ERK MAPK pathway. ERK MAPK activity (pERK) is required for proper hippocampus-dependent cognitive performance.
We found that during memory consolidation Tg2576 treated with RTZ exhibit increased hippocampal PPARγ in the nucleus that associates with pERK. Furthermore, PPARγ antagonism via the irreversible, selective, full antagonist GW9662 disrupts both the pERK-PPARγ

complexes and cognitive rescue in RTZ-treated Tg2576. We further demonstrate that these novel nuclear pERK-PPARγ complexes are elevated under steady state conditions in untreated Tg2576 mice with higher cognitive function, indicating a correlation between high complex levels and high cognitive ability. Thus, in AD mice the RTZ-mediated increase in nuclear pERK-PPARγ complexes serves a compensatory role by increasing pERK activity in the nucleus during memory consolidation. Finally, in a manner similar to Tg2576 brain, a correlation was also found in human cortex between the amount of pERK-PPARγ complex and the severity of AD (MMSE score).

Title: Phosphodiesterase-4A knockout protects against abeta42-induced memory decline

Authors: *R. HANSEN, III[1], Q. WU[2], C. WANG[2], M. CONTI[3], H.-T. ZHANG[2]
[1]Neurobio. and Anat., [2]Behavioral Med. and Psychiatry , Physiol. & Pharmacol., West Virginia Univ., Morgantown, WV; [3]Obstetrics & Gynecology, Univ. of California, San Francisco, CA

Abstract: Alzheimer’s disease (AD) is a debilitating dementia currently affecting ~ 5 million Americans resulting in the 6th leading cause of death in this country. The main pathological hallmark of AD is the accumulation of amyloid plaques in the brain which are comprised of beta-amyloid peptides 1-40 (Abeta40) and 1-42 (Abeta42). Despite years of research and numerous failed clinical trials, there are still no effective drugs to alleviate symptoms in AD such as memory loss, or underlying pathology such as plaque accumulation and neuron/synapse loss. Interestingly, AD has been shown to significantly suppress cAMP signaling resulting in decreased levels of the nootropic transcription factor CREB. Inhibition of phosphodiesterase 4 (PDE4), a family of enzymes responsible for the hydrolysis of cAMP, may provide a novel potential therapeutic in AD by raising cAMP levels. PDE4A, which is one of four subtypes

(PDE4A-D), is strongly expressed in the hippocampus which is particularly affected in AD; however, the functional role of PDE4A has not been investigated. The purpose of this study was to identify the role of PDE4A in memory loss associated with AD through the use of PDE4A knock out (KO) mice. This study was conducted by injecting Abeta42 into the hippocampus of PDE4A KO mice and wild type (WT) controls and after 2 weeks recovery, memory analyzed by the step through passive avoidance test. In addition, cAMP/phospho-CREB (pCREB) levels were also analyzed to identify molecular correlates involved. PDE4A KO significantly attenuated the memory deficits caused by Abeta42 infusions into the hippocampus as seen in passive avoidance. Also, PDE4A KO resulted in a significant increase of cAMP and pCREB levels and attenuated the down expression of pCREB caused by Abeta42 injection. In conclusion, PDE4A inhibition may represent a novel nootropic for the treatment of AD related memory loss.

Title: Acute and repeat dosing with pioglitazone produces changes in resting state brain functional connectivity in awake rats

Authors: *K. E. ASIN[1], D. CRENSHAW[2], K. GOTTSCHALK[2], N. ZHANG[3], Z. LIANG[3], A. ROSES[2]

Abstract: Pioglitazone HCl (PIO) is a thiazolidinedione (TZD) PPARγ receptor agonist approved for treatment of type 2 diabetes (T2D). In addition to reducing peripheral insulin resistance, evidence suggests that PIO improves or protects neuronal mitochondrial function and increases mitochondrial biogenesis. TZDs are reported to ameliorate some of the cognitive deficits seen in murine models of Alzheimer’s disease (AD) and in humans with AD, and have been proposed for the treatment or prevention of AD. This abstract reports the effects of low-dose PIO treatment on resting state functional connectivity (FC) in the brains of awake rats.

Resting state FC reflects temporal correlations in spontaneous fluctuations in hemodynamic activity across brain regions, as measured using blood oxygen level-dependent (BOLD) functional MRI.
Awake, adult male Wistar rats were acclimated to the scanning procedure for ~7 days. After acclimation, a baseline scan was performed using a 4.7 Tesla/40cm horizontal magnet and BOLD imaging 2.5-3h after dosing with citric acid (Veh). Thereafter, rats were administered Veh or PIO orally at doses estimated to provide plasma exposures equivalent to treating humans with 1.5, 3, 6 or 12 mg/day. One group of Veh- and one group of PIO-treated rats were scanned after the 2nd dosing; all rats were scanned after the last (7th) daily dose (n=5/group).
Each brain was demarcated into 57 regions of interest (ROIs). The time course of each ROI was extracted and cross-correlation coefficients between all pairs of ROIs were calculated to evaluate functional connectivity. Using a repeated measures ANOVA, it was demonstrated that 17 ROI pairs showed significant ($P<0.005$, uncorrected) changes in functional connectivity on Day 7 of treatment with PIO (all dose groups combined) compared with Veh. Greatest FC changes were seen between the midline nuclei of the dorsal thalamus and somatosensory cortex, and the lateral nuclei of the dorsal thalamus and globus pallidus. Significant changes also were seen in 2 pairs of ROIs on day 2 of dosing. A voxel-by-voxel analysis indicated increased connectivity between the CA1 region of the hippocampus as the seed and the hypothalamus and ventral thalamus after 7 days of dosing; changes in connectivity were least apparent at the highest dose.
Our results indicate that PIO at doses lower than those used to treat T2D leads to changes in FC in conscious rats within 2 days of treatment. These results provide preliminary evidence that low doses of PIO cross the blood brain barrier and change brain physiology, and support the hypothesis that this drug may be a beneficial pharmacotherapy for neurodegenerative diseases such as AD.

Title: DAla2-GIP reduces amyloid plaque load, oxidative stress and inflammation in APP/PS1 transgenic mice.

Authors: *A. DUFFY[1,2], C. HÖLSCHER[2]
[1]Derry, United Kingdom; [2]Biomed. Sci., Univ. of Ulster, Coleraine, United Kingdom

Abstract: Alzheimer's disease (AD) is a neurological disorder characterized by formation of senile plaques and neurofibrillary tangles with an associated decline in cognitive function. Substantial evidence also shows the significant role of inflammation and oxidative stress in the pathogenesis of AD. The exact cause of the disease remains unknown, but recently T2DM has been identified as a risk factor. Glucose-dependent insulinotropic polypeptide (GIP), an incretin hormone released from intestinal K cells, has been shown to regulate insulin secretion in diabetic patients and is produced in neurons. It has recently been shown that the long lasting incretin hormone analogue DAla2GIP has growth factor properties and is successful in improving synaptic plasticity, cell proliferation and neurogenesis. This study investigates the effect of DAla2GIP on amyloid plaques, oxidative stress and inflammation in the APP/PS1 mouse model of AD.

12 & 19month old male APP/PS1 mice were injected with DAla2GIP (25 nmol/Kg)/saline once daily for 35 days. Immunohistochemistry was performed for GFAP, a marker for astrocytes, and 8-oxoguanine, a marker for oxidative stress, in the cortex and CA1 & CA3 regions of the hippocampus. Beta amyloid plaque load was measured using a specific antibody.

There were significant reductions of beta amyloid plaques and oxidative stress in the cortex of 12month old mice when treated with DAla2GIP compared to saline, $P<0.02$ & $P<0.01$ respectively. In 19month old mice there were again significant reductions of beta amyloid plaques and oxidative stress as well as in GFAP positive astrocytes, $P<0.001$ beta amyloid & 8-oxoguanine, $P<0.01$ GFAP. Similar results were found in CA1 & CA3 of the hippocampus. In CA1 at 12 & 19months, there were significant reductions in the amount of oxidative stress in drug treated mice compared to saline, $P<0.01$. Again in the CA3 region there were reductions in both age groups after DAla2GIP injections, $P<0.01$ 12months, $P<0.05$ 19months. There were significantly less GFAP positive astrocytes in CA1 at 12 & 19months, $P<0.01$ & $P<0.05$ after DAla2GIP treatment compared to saline. In the CA3 region, GFAP positive astrocyte levels were also significantly lower after drug treatment, $P<0.01$ & $P<0.05$. Data for 6 month old mice will be available on poster at conference, along with data analyzing the effect of a double knockout of GIPR and GLP-1R on learning and memory.

This study shows that the long lasting GIP receptor agonist DAla2GIP significantly reduces the hallmarks of AD and has potential to be developed as a therapeutic treatment. Interestingly, the drug has effect in both the moderate and later more severe stages of the disease.

Title: HDAC inhibition improves abnormal neuronal functions in Alzheimer’s disease model Tg6799 mice

Authors: *H. NOH, H. SEO
Dept. of Mol. and Lifescience, Hanyang Univ., Ansan, Gyeonggi, Korea, Republic of

Abstract: The AD model Tg6799 transgenic mice overexpress mutant human APP (695) with the Swedish (K670N, M671L), Florida (I716L) and London (V717I) mutations and mutant human PS1 (M146L and L286V). To determine the effects of histone deacetylase (HDAC) inhibition in AD, valproic acid (VPA) were administered in Tg6799 mice. Three different age groups of 1, 5, and 10 months were tested for pre-symptomatic, early symptomatic, and late symptomatic stages. The blood and brain samples were isolated from Tg6799 mice for RT-PCR and Western blot analysis. The mRNA levels of IL-1β and NF-kB increased in plasma of Tg6799 mice at pre-symptomatic stage. In the hippocampus of Tg6799 mice, the mRNA levels of IL-1β and APOE increased at 10 months of age, compared to littermate control. VPA decreased the mRNA levels of IL-1ß and APOE in the hippocampus of Tg6799 mice at 10 months of age. In addition, VPA altered NGF expression levels in hippocampus of Tg6799 mice at 5 and 10 months of age. Moreover, VPA decreased the escape latency of Tg6799 mice in Morris Water Maze assessment at 5 months and 10 months of age. These data suggest that inhibition of histone deacetylation can improve neuronal function through trophic regulation in AD model.

Title: Evaluating two novel calorie restriction mimetics for treating alzheimer's disease

Authors: P. J. PISTELL[1], K. MANAYE[2], T. UTSUKI[3], J. DOWDEN[3], B. RAY[5], D. LAHIRI[5], *D. K. INGRAM[4]
[1]Psychology, Towson Univ., Towson, MD; [2]Dept. of Physiol. and Biophysices, Col. of Med. , Howard Univ., Washington, DC; [3]Nutritional Neurosci. and Aging, Pennington Biomed. Res. Ctr., Baton Rouge, LA; [4]Nutritional Neurosci and Aging, Pennington Biomed. Res. Ctr., BATON ROUGE, LA; [5]Dept. of Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract:
We aim to assess the efficacy of candidate calorie restriction (CR) mimetics as possible treatments for Alzheimer's disease (AD) characterized by excessive brain amyloid-beta (Aβ) peptide derived from the Aβ precursor protein (APP). In various animal models, CR (30-40% reduction in caloric intake) has been shown to retard pathogenesis of AD, and epidemiological studies have indicated that dietary calories consumed are inversely related to risk of the disease. CR mimetics are being designed to provide the anti-aging effects of CR without requiring actual reduction in calories. A few candidate CR mimetics have been successfully evaluated in transgenic mouse models of AD by other investigators, including resveratrol as an activator of SIRT1, rapamycin, as an inhibitor of mTOR, and 2-deoxyglucose (2DG) as a glycolytic inhibitor. Using a double transgenic mouse model of AD ($APP_{swe}/PS1_{\Delta\varepsilon 9}$), we are evaluating an inhibitor of glucose metabolism, the 7-carbon sugar mannoheptulose (MH), and a citric acid cycle intermediate, oxaloacetate (OX), targeted to increase intracellular levels of NAD+. These compounds were separately incorporated into the diet at 3 mo of age. We also employed a CR group by feeding mice every-other-day (EOD). At
8-9 months mice were evaluated for cognitive function and pathology. Notably, similar to EOD fed mice, those on MH diet (1700 mg/kg delivered as an extract of avocado) had reduced body weights relative to mice on control diet as well as reduced body fat and blood cholesterol. However, unlike mice on EOD feeding, mice fed MH diet ad libitum had food intake similar to controls. Mice on OX diet (350 mg/kg) also did not differ from controls in food intake nor in cholesterol levels, body weight or
composition. Mice on EOD, MH, and OX diets exhibited improved learning ability in a complex

maze task (Stone maze) compared to mice on control diets. Preliminary stereological analysis of Aβ pathology reveal a significant positive correlation between hippocampal Aβ plaque load and maze errors, with mice on experimental diets showing reduced pathology and less errors. Separately, secreted fraction of the hippocampal extract was prepared at 100,000xg for 1 hr, and subjected to different biochemical analyses. Western immunoblotting reveals that the non-amyloidogenic
sAPPα level was significantly increased in the EOD and OX groups relative to controls, consistent with behavioral results. Thus, these candidate CR mimetics appear to ameliorate both functional and pathological manifestations of AD modeled in these mice similar to CR, and these beneficial effects on the disease do not require reduced food intake or necessarily changes in body composition.

Title: Effects of estradiol-quinol treatment on a murine model of Alzheimer’s disease.

Authors: *A. E. SCHLAPPAL[1,2], R. SCHUH[3,4], L. PROKAI[5], M. OTTINGER[2]
[1]Neurosci. and Cognitive Sci. Grad. Program, Univ. of Maryland, College Park, MD; [2]Animal and Avian Sci., Univ. of Maryland, College Park, MD; [3]Res. and Develop., VA Maryland Hlth. Care Syst., Baltimore, MD; [4]Neurol., Univ. of Maryland Sch. of Med., Baltimore, MD; [5]Mol. Biol. and Immunol., Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: The neuroprotection offered by estrogens provide a potential candidate for therapeutic interventions applicable for Alzheimer’s disease (AD). However, clinical applications must provide the benefits of estradiol without deleterious peripheral effects of estradiol. Estrogen-derived para-quinol compounds are prodrugs of estrogens that deliver estradiol centrally; no stimulatory effects of e-quinol are observed. The transgenic murine AD model used in this study over-expresses human mutant forms of amyloid precursor protein (APP) and presenilin 1 (PS1). Female APP/PS1 transgenic mice and non-transgenic litter mates (6 months) were treated with

vehicle (propylene glycol), estradiol (E2; 2ug/day), or E2-quinol (E2Q, 2ug/day). Treatments were administered over 8 weeks using Alzet osmotic pumps (0.25ul/min); behavioral tests were conducted and tissue collected. Uterine wet weight was examined as an indirect measure of circulating E2. Amyloid beta 1-40/1-42 levels were measured in whole brain homogenates using an ELISA and full length APP (6E10) was assessed by western blot. Superoxide dismutase, and catalase enzyme activity and protein carbonylation were measured to assess oxidative damage. Results showed behavioral measurements were not significantly different between groups. APP/PS1 mice treated with E2-quinol have reduced uterine wet weight compared to APP/PS1 mice treated with E2, indicating low circulating E2. Additionally the ratio of 40:42 amyloid fragments is reduced in E2Q treated mice indicating a positive effect of treatment on overall amyloid load. Finally, oxidative stress markers are altered in E2Q treated mice as compared to control animals, suggesting a beneficial role for the quinol. Our findings support the possibility that E-quinol compounds have potential as an intervention that would benefit AD patients.

Title: Intraperitoneal and intranasal formulations of erythropoietin (EPO) showed potent protective activity against amyloid toxicity in the oligomeric Aβ25-35 nontransgenic mouse model of Alzheimer's disease

Authors: *T. MAURICE[1], M.-H. MUSTAPHA[1], M. DE LA C GARCÍA-BARCELÓ[2], Y. RODRIGUEZ CRUZ[2], J. GARCIA RODRIGUEZ[3]
[1]INSERM U.710, Montpellier, France; [2]Histology Department. Preclinical and Basic Sci. Inst., Havana Med. Univ., Habana, Cuba; [3]Scientific Advisor´s State Council, Habana, Cuba

Abstract: Human recombinant erythropoietin (rHu-EPO) has been employed in the treatment of renal insufficiency associated anemia and in cancer patients suffering chemo- and radiotherapy-induced anemia. Besides its role in erythropoiesis, rHu-EPO is a potent cell protectant and it showed a strong potential in protecting brain cells from ischemic injury or from toxicity observed in neurodegenerative pathologies, including Alzheimer's disease (AD). Different types of EPO without erythropoiesis-stimulating activity have been developed, including rHu-EPO with low sialic acid content (Neuro-EPO). This latter form allows intranasal (IN) delivery, which

avoid systemic administration related potential side effects. In this study, we compared the neuroprotective ability of intraperitoneal (IP) administration of rHu-EPO and IN injection of Neuro-EPO against amyloid toxicity in mice, that received an intracerebroventricular injection of oligomeric amyloid(25-35) peptide (oAß), a validated model of AD-like pathology. oAß was administered at day 0, rHu-EPO, 125-500 µg/Kg IP, was administered once a day between day 1 to 4 and Neuro-EPO, 62-250 µg/Kg IN, was injected three times a day between day 1 to 4. Memory deficits were analyzed between day 7 to 12, using the spontaneous alternation, passive avoidances and water maze procedures. In hippocampus or cortex extracts prepared at day 7, the levels of peroxidation of membrane lipids and the level of cholinesterase activity were analyzed as markers of the oxidative stress and cholinergic activity loss. A histochemical approach is used to adress brain morphological damages and inflammation. Data showed that rHu-EPO significantly protected from oAß toxicity, on all reponses and markers examined, at the doses of 250 µg/Kg IP and higher. Neuro-EPO showed a similar efficacy, at doses of 125 µg/Kg IN and higher, outlining the potential of the IN route.

Title: Peripherally administered antibody against apolipoprotein E: Effects on amyloid-β pathology in a mouse model of Alzheimer disease

Authors: *F. LIAO, T. E. MAHAN, H. JIANG, J. KIM, D. HOLTZMAN
Neurol., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: In the search for a treatment for Alzheimer's disease (AD), one focus has been on decreasing accumulation of amyloid-β (Aβ) in the brain by reducing Aβ production, enhancing its clearance or inhibiting its aggregation. Apolipoprotein E (apoE) plays an important role in modulation of AD pathogenesis by interacting with Aβ to affect its clearance and aggregation.

Amyloid precursor protein (APP) transgenic mice on a mouse apoE null background have lower plaque load and much less to no fibrillar Aβ compared with APP mice expressing endogenous murine apoE. Haploinsufficiency of human and murine apoE reduces amyloid deposition in APP transgenic mice. Overexpression of low-density lipoprotein receptor (LDLR) which binds to and clears apoE results in a decrease of both apoE level and Aβ accumulation. The goal of this study is to test whether monoclonal antibodies directed against apoE can decrease Aβ accumulation as well as decrease existing Aβ aggregates and associated pathology. When the anti-apoE mouse monoclonal antibody HJ6.3 was administered on a weekly basis intraperitoneally beginning prior to Aβ accumulation it significantly decreased Aβ accumulation as assessed both histologically and well as biochemically as compared to phosphate-buffered saline (PBS) treated PS1δE9/APPswe transgenic mice. We also administered HJ6.3 at a dose of 10 mg/kg/weekly or PBS intraperitoneally to PS1δE9/APPswe transgenic mice beginning at 7 months of age (after Aβ accumulation has already started) for 21 weeks. Two days after the final injections, the brains were processed for histological and biochemical studies. Our preliminary results suggest that compared to PBS injected mice, that anti-apoE antibody HJ6.3 significantly decreases Aβ in both the hippocampus and cortex. These results suggest that apoE, a protein involved in Aβ metabolism, may be a novel target for an immunotherapy approach for Alzheimer's disease.

Title: Restoration of mitochondrial dynamics attenuates neurological and memory phenotype in AD mice *in vivo*.

Authors: *E. TRUSHINA[1], I. MAEZAWA[2], L.-W. JIN[3], D. H. HUA[4]
[1]Dept. of Neurol., Mayo Clin. & Fndn., Rochester, MN; [2]Pathology, [3]Pathology,, Univ. of California Davis, Sacramento, CA; [4]Chem., Kansas State Univ., Manhattan, KS

Abstract: Aggregation of intracellular amyloid beta (Aβ) has been shown to directly affect mitochondrial dynamics, morphology and function in multiple cellular models of Alzheimer's Disease (AD). However, it is not clear to what extent alterations in mitochondrial dynamics contribute to the progression AD. We have demonstrated that cell-permeable tricyclic pyrone compound CP2 efficiently prevents Aβ aggregation in cellular and animal models of AD reducing cell death associated with intracellular Aβ oligomers. CP2 penetrates blood brain barrier and do not cause adverse side effects when administered to animals. We have also demonstrated using three transgenic animal models of familial AD (FAD) that alterations in mitochondrial dynamics and function occur early in AD progression and preclude the onset of memory phenotype and amyloid plaque formation. To test whether blocking Aβ aggregation and oligomerization could attenuate the onset and progression of AD in vivo, we administered CP2 via drinking water to a cohort of FAD mice carrying a single APP or PS1 mutation, and double mutant APP/PS1. Mice were treated for 4 and 13 months. CP2-treated animals were allowed to breed producing progeny that were on CP2 from birth. CP2-treated animals gain weight, breed, groom, and behave similar to the untreated littermates. All CP2-treated mice were examined for the onset of neurological and memory phenotype, amyloid load, and mitochondrial dynamics and morphology. Mice that were on either short- or long-term CP2 treatment were indistinguishable from non-transgenic littermates in their performance in memory (novel object recognition test) and neurological assessments (rotarod and hanging bar test), while untreated FAD mice demonstrated substantial decline in all tests. As expected, CP2 treatment significantly reduced amyloid load in the brain of FAD animals. Moreover, CP2 treatment completely restored mitochondrial dynamics that was altered in embryonic neurons from FAD mice. Electron microscopy examination revealed significant reduction in mitochondria with altered morphology in the brain of CP2-treated FAD mice comparing to untreated animals. Taken together, these results demonstrate that restoration of mitochondrial dynamics early in disease progression rescues AD phenotype in vivo in multiple animal models of FAD validating mitochondrial motility as an early therapeutic target in AD.

Title: Two protein prenylation pathways exhibit differential effects in a mouse model of Alzheimer's disease

Authors: *S. CHENG[1], D. CAO[1], F. WANG[1], D. HOTTMAN[1], E. LEATHLEY[1], W. ZHANG[1], M. PARENT[1], L. HOVDE[1], M. BERGO[2], L. YUAN[1], L. LI[1]

Abstract: Many intracellular proteins are posttranslationally modified with a 15-carbon farnesyl or 20-carbon geranylgeranyl lipid at a carboxyl-terminal *CAAX* motif. The reactions, collectively called protein prenylation, are carried out by protein farnesyltransferase (FT) and protein geranylgeranyltransferase type I (GGT) and render the protein hydrophobic, promoting membrane anchoring and protein-protein interactions. Prenylated proteins regulate a wide range of cellular processes, such as cell growth, differentiation, cytoskeletal organization, and vesicle trafficking. Isoprenoid lipids and prenylated proteins have been implicated in the pathophysiology of Alzheimer's disease (AD), including amyloid-beta (Abeta) precursor protein (APP) metabolism, tau phosphorylation, synaptic plasticity, and neuroinflammation. However, the precise role of protein prenylation in AD pathogenesis remains to be determined. In this study, we bred FT and GGT heterozygous knockout (+/-) mice with AD mice (B6C3-Tg(APPswe,PSEN1dE9)85Dbo/J; APP/PS1) to assess the impact of decreasing protein prenylation levels on the development of AD-like learning/memory impairment and neuropathology. In the Morris water maze test, we found that decreasing FT activity rescued spatial learning and memory function in APP/PS1 mice. In contrast, decreasing GGT activity had no impact on spatial learning and memory impairment. Our preliminary data also suggest that FT and GGT deficiencies exert differential effects on synaptic plasticity in the hippocampus, with an increased magnitude of long-term potentiation (LTP) in FT+/- mice but a decreased LTP magnitude in GGT+/- mice. These results are consistent with our recent findings that a farnesyltransferase inhibitor, but not a geranylgeranyltransferase inhibitor, enhances hippocampal LTP in mice. Biochemical analyses are underway to determine the effects of FT and GGT haploinsufficiency on Abeta deposition and neuroinflammation. Our findings suggest that farnesylated and geranylgeranylated proteins exhibit differential effects on the pathogenesis of AD and that inhibiting FT activity may be a viable strategy to treat AD.

Title: Mitochondrial protection is induced by the novel tetrahydrofuran derivative ANAVEX2-73 after ICV injection of oligomeric Aß25-35 peptide in mice, a nontransgenic Alzheimer's disease model

Authors: *V. LAHMY[1,2], R. LONG[3], D. MORIN[3], V. VILLARD[2], A. VAMVAKIDES[4], T. MAURICE[1]
[1]Univ. Montpellier 2 Inserm U710, Montpellier Cedex 5, France; [2]AMYLGEN, Clapiers, France; [3]INSERM U955, CRETEIL, France; [4]ANAVEX Life Sci., Pallini, Greece

Abstract: Tetrahydro-N,N-dimethyl-2,2-diphenyl-3-furanmethanamine hydrochloride (ANAVEX2-73) is a novel compound binding to muscarinic acetylcholine and sigma-1 receptors with affinities in the low micromolar range. We previously reported that the drug showed anti-amnesic and neuroprotective potential in the Alzheimer's disease (AD) model in mice induced by the icv injection of oligomeric amyloid(25-35) peptide (oAß25-35). In particular, the drug attenuated the oxidative stress, caspases induction, cellular loss, Aß1-42 seeding, Tau hyperphosphorylation and learning and memory deficits observed several days after oAß25-35 injection. Excessive mitochondrial fragmentation may also be a triggering event in AD physiopathology as mitochondrial dysfunction is consistently reported in brains of AD patients and transgenic mice. Indeed, oAß induce Ca2+-dependent reactive oxygen species generation in neurons and elicit Ca2+ entry through NMDA receptors, producing abnormal Ca2+ signals that in turn promote mitochondrial fission. In mitochondrial-endoplasmic reticulum contact sites (MAM), localized Ca2+ changes occur in microdomains, in which mitochondria operate as a barrier Ca2+ buffer. Sigma-1 receptors act precisely as molecular chaperones regulating Ca2+ effluxes at MAM. We therefore analyzed ANAVEX2-73 impact on mitochondrial markers in hippocampus extracts of oAß25-35-treated mice. oAß25-35 induced a time-dependent increase in cytochrome c release, at 1, 3, 5 days after injection, with a return to basal at day 7. This was

accompanied with increases in Bax levels, significant at day 3 and 5, no change in Bcl-2 levels, and significant increases in Bax/Bcl-2 ratio at days 5 and 7 after injection. In parallel, an increase in lipid peroxidation levels, at days 5 and 7, and in caspase-9 expression, at day 7, were measured. At day 5 after injection, mitochondrial respiration was examined by oxymetry and found to be significantly altered in oAß mice. Treatment with ANAVEX2-73, in the 0.1-1 mg/kg ip dose range, restored all parameters examined. The effect of the selective reference sigma-1 agonist PRE-084 is currently under investigation. This study delineates the mitochondrial damage induced in the oAß25-35 mouse model of AD and showed that an effective mitochondrial protection is induced by the tetrafuranmethanamine derivative.

Title: Rosiglitazone-dependent rescue of intrinsic excitability deficits in dentate granule cells of Tg2576 mice

Authors: *M. N. NENOV[1,2], C. HERNANDEZ[1,2,3], K. DINELEY[1,2,3], F. LAEZZA[4,2,3]

Abstract: Emerging evidence indicates a strong link between cognitive deficits that characterize early stages of Alzheimer's disease (AD) and insulin resistance. However, the mechanistic link between these two diseases is as yet unknown. Clinical studies have shown that pharmacologic agents such as Rosiglitazone (RSG) which activate the peroxisome proliferator-activated receptor-gamma (PPARgamma) improve insulin signaling and can effectively ameliorate cognitive function in AD mouse models and in a subset of AD patients. While some current PPAR gamma agonists have demonstrated adverse effects, establishing a mechanistic link between RSG and cognitive improvement could open the way to a new generation of therapeutics against cognitive decline in AD.

Building on previous results from our group demonstrating that one month RSG treatment rescues cognitive function in the Tg2576 AD mouse model, we now present new data showing that this cognitive rescue is accompanied by restored firing of granule neurons in the dentate gyrus, a critical area of the hippocampal circuit implicated in AD etiology. Passive properties and intrinsic excitability were examined in dentate granule neurons of 9 month old Tg2576 and age matched wild type mice either untreated or treated with RSG. We found that RSG treatment normalizes resting membrane potential, firing frequency, and the action potential voltage threshold partially compensating for a loss in excitability observed in Tg2576 mice. Our data suggest that RSG-dependent cognitive rescue might take place through a global functional rescue of the DG circuit by normalizing synaptic activity (see abstract from Laezza et al.) and intrinsic excitability.

Title: Tau immunotherapy alone or in conjunction with beta-amyloid immunotherapy reduces gallyas positive neurofibillary tangles

Authors: *K. C. WALLS, R. AGER, R. MEDEIROS, F. M. LAFERLA
Neurobio. and Behavior, UC Irvine, Irvine, CA

Abstract: Alzheimer’s disease is pathologically characterized by the accumulation of beta-amyloid (Aß) plaques and tau-laden neurofibrillary tangles (NFTs). To date, human clinical trials in humans indicate that clearance of Aß plaques does not improve cognition, and at best may stabilize cognitive decline. These types of results highlight the need to identify and focus on other aspects of AD pathology, with tau representing a high value target that has been understudied. Since the 3xTg-AD mice develop both plaques and tangles, we investigated the utility of concomitantly targeting both Aß and tau using immunotherapy approaches. The diverse phosphorylation states that tau can undergo complicates the selection of the appropriate antibody, but a large body of work indicates that the serine/threonine targets comprising the AT8

epitope may be the most pathologically relevant. Hence, we used an antibody that recognizes serine 199 and threonine 202 phospho-tau (the AT8 epitope). As expected, Aß immunotherapy effectively reduced Aß plaques and intracellular Aß. Here we report the novel finding that tau immunotherapy reduced somatodendritic tau and silver stained (Gallyas) positive neurons, without affecting Aß pathology. This result occurred whether tau immunotherapy was administered alone or in combination with Aß immunotherapy. We assessed the temporal reoccurrence of tau pathology after immunotherapy by performing a time course. Our results showed combining Aß and tau immunotherapies delayed somatodendritic tau and NFT accumulation versus tau immunotherapy alone. In conclusion, our results show combining Aß- and tau-directed therapies has a synergistic effect on reducing tau pathology. These studies provide compelling evidence that targeting both tau and Aß represents an effective treatment strategy for Alzheimer's disease.

Title: Efficacy of an antigen sensitized dendritic cell vaccine against Alzheimer's disease is effected by injection type.

Authors: *N. R. NABAR[1,2], X. LIN[2], S.-F. ZHOU[3], C. CAO[2]
[1]Univ. of South Florida, Tampa, FL; [2]USF Hlth. - Byrd Alzheimer's Inst., Tampa, FL; [3]Dept. of Pharmaceut. Sci., USF Col. of Pharm., Tampa, FL

Abstract: As demonstrated by the AN-1792 clinical trial, vaccine development against Alzheimer's disease (AD) has shown positive results with regards to efficacy, but has faced major challenges in avoiding the potential adverse effects. Currently, all anti-amyloid beta (Aβ) vaccines in clinical trials use only the Aβ B-cell epitope in hopes of circumventing production of a Th1 inflammatory response. In the past, our lab has aimed to develop a vaccine against AD which utilizes both the B-cell and T-cell epitopes, and our efforts have led to the development of an antigen sensitized dendritic cell (DC) vaccine. In production of our vaccine, DCs are isolated from the donor, cultured with IL-4, and sensitized to either wild-type or a mutated Aβ peptide ex vivo. The sensitized DCs are then injected into mice via I.P. injection or i.v.. Studies in BALB/c,

PDAPP, and APP/PS1 mice have shown a sustained antibody titer is elicited when a mutated Aβ peptide is used for sensitization, but no antibody titer is elicited when wild type Aβ is used. In this study, we looked to investigate the difference in antibody response when our DC vaccine is injected via I.P., I.V., and subcutaneous injection in male BALB/c mice. As expected, DCs sensitized with wild-type Aβ was not able to elicit an antibody titer when administered through I.P or I.V. injection. Interestingly, when DCs sensitized with wild-type Aβ were injected into the subcutaneous region without adjuvant, an antibody titer was elicited. We hypothesize that antigen presentation mechanistically differs in the subcutaneous region compared to the peritoneum or the vasculature, allowing Aβ to be presented as an antigen by the dendritic cell. Moreover, the inability of immune cells in the subcutaneous region to recognize wild-type Aβ as a self antigen in the subcutaneous region may have broader implications related to its physiological function and regulation.

Title: Increased glial glutamate transporter EAAT2 expression ameliorates Alzheimer’s-like pathologies, premature death, and memory deficits in $APP_{Sw/Ind}$ mice

Authors: *Q. KONG, K. TAKAHASHI, Y. LIN, D. SCHULTE, C.-L. G. LIN
The Ohio State University, Dept. of Neurosci., Columbus, OH

Abstract: Many reports have demonstrated that the glutamate uptake system is impaired in Alzheimer’s disease (AD) brains and that decreased glutamate uptake activity is associated with decreased glial glutamate transporter EAAT2 protein expression. Excessive glutamate can cause over-stimulation of glutamate receptors and subsequently lead to excitotoxic neuronal damage. Loss of EAAT2 protein and associated function was also observed in transgenic models of AD. However, it is still unknown whether EAAT2 dysfunction contributes to the pathogenesis of AD. In the present study, we crossed EAAT2 transgenic mice, which have a 1.5-2 fold increase in EAAT2 protein levels as compared to their non-transgenic counterparts, with the $APP_{Sw/Ind}$ mice

to investigate whether supplementation of the loss of EAAT2 would have beneficial effects on disease progression. As we expected, EAAT2 protein level and the associated glutamate uptake functions were restored in APP/EAAT2 double transgenic mice compared to their APP transgenic littermates. Several striking phenomena were observed in APP/EAAT2 mice compared with APP mice. First, premature death was significantly reduced. Second, learning and memory capacity was significantly improved. Third, several Alzheimer's-like pathological changes were significantly reduced. These results indicate that loss of EAAT2 contributes to the pathogenesis of AD and suggest that enhanced glutamate uptake by increasing EAAT2 expression may be a potential therapeutic strategy for AD.

Title: ACU-193: A drug candidate antibody selectively recognizing soluble abeta oligomers.

Authors: *G. A. KRAFFT[1], F. HEFTI[2], W. GOURE[2], J. JERECIC[2], K. IVERSON[2]
[1]Acumen Pharmaceuticals, GLENVIEW, IL; [2]Acumen Pharmaceuticals, Livermore, CA

Abstract: Soluble Abeta oligomers inhibit synaptic function, trigger early memory deficits, initiate nerve cell degeneration and are now recognized as key culprits in Alzheimer's disease. Also known as ADDLs (Abeta-Derived Diffusible Ligands), these neurotoxic assemblies represent a highly attractive point of intervention for effective treatment of Alzheimer's patients. In this presentation we report on a promising new drug candidate, ACU-193, which targets ADDLs directly and with high selectivity, preventing their attack on susceptible neurons. ACU-193 is a humanized, affinity matured IgG2 monoclonal antibody, engineered to minimize cellular effector functions and immunogenicity. ACU-193 binds ADDLs with affinities ranging from <0.8 nM to 9 nM, as measured by surface plasmon resonance (Biacore) and various ELISA methods, respectively. In competitive assays with ADDLs and Abeta monomer, ACU-193 exhibits 550-fold preferential binding for ADDLs, and it does not exhibit any cross-reactive binding to other proteins.
In vitro efficacy of ACU-193 was demonstrated by potent inhibition (IC50 = 1-5nM) of ADDL binding to cultured hippocampal neurons, whereas other Abeta-directed antibodies either fail to

inhibit this binding or exhibit substantially lower potency. In vivo target engagement and efficacy of ACU-193 was demonstrated in the Tg2576 transgenic AD mouse model. Following intravenous administration of ACU-193 (10-50mg/kg), dose-dependent complex formation with ADDLs in brain tissue was demonstrated, and initial evidence of beneficial behavioral effects emerged from experiments that measured nocturnal hyperactivity of the Tg2576 mice.
In several animal species, ACU-193 showed linear, dose-dependent pharmacokinetics, biodistribution, and brain penetration in the range of values that are typical for therapeutically used antibodies. Exploratory safety and toxicity studies revealed an overall excellent safety profile of ACU-193. Stable, high-yielding cell lines have been established for efficient production of ACU-193.
Two biomarker assays have been generated to support future clinical studies of ACU-193. First, an ELISA measuring ACU-193/ADDL complexes in CSF may provide a pharmacodynamic readout, and, second, an ultrasensitive ELISA measuring ADDL levels in CSF from human subjects should enable patient selection and stratification and serve as a companion diagnostic. Because ADDLs trigger acute and persistent synaptic malfunction, ACU-193 treatment may restore normal synaptic function and improve cognitive function in Alzheimer patients.

Title: Chronic treatment with the GLP1 analogue Liraglutide increases cell proliferation and subsequent differentiation to neuronal phenotype in an AD mouse model.

Authors: *V. PARTHSARATHY, C. HOLSCHER
Univ. of Ulster, Coleraine, United Kingdom

Abstract: Background: Neurogenesis is a life long process, but the rate of cell proliferation and differentiation decreases with age. In Alzheimer’s patients, along with age, the presence of Aβ in

the brain inhibits this process by affecting the pathways of stem cell proliferation, differentiation and decreasing the survival of the cells by activating pro apoptotic pathways. Neuronal progenitors are found to have incretin hormone receptors and GLP1 mimetic, Liraglutide (Victoza^{TM}, NovaNordisk) have shown to increase cell proliferation in mouse model of AD. Here we investigated acute and chronic effects of Liraglutide on progenitor cell proliferation and differentiation of these newly generated cells to neurons in the dentate of WT and APP/PS-1 mice model at different ages. For this, APP/PS1 and their littermate female mice, aged 3, 6, 12, 15 months were injected i.p. with 50mg/kg/body wt of 5-Bromo-2'deoxyuridine (BrdU) for 7 days and were subsequently injected with 0.9% NaCl (w/v) or 25nmol/Kg Liraglutide for 7 days in case of acute treatment, or 30 days for Chronic treatment. The animals were perfused and brain harvested after 4 weeks of last BrdU injections. Immunohistochemical and double immunofluorescent studies were carried out for detection of cell proliferation (BrdU) and cell differentiation (NeuN, GFAP, Iba1) in coronal sections and the cells were counted in the dentate gyrus. Our study shows that there was no difference in the number of newly generated cells in wild type littermate control in both acute and chronic treated animals at age 3, 6 months and acute treated animals of 12, 15 months of age. Chronic treatment of 12 and 15 months WT mice showed significant increase in new cells compared to saline treatment (student t test, $p<0.05$). In AD mouse brains no difference was seen in acutely treated 3 months old mice. Increase in number of new cells were seen in chronically treated 3 month group ($p<0.01$) and in both acutely and chronically treated 6, 12, 15 months groups. In the dentate, most newly generated cells differentiated into neurons with very few converting to astrocyte and microglia. No difference in number of newly differentiated neurons was seen in WT groups at all ages ($p>0.05$). Significant increase in neuronal phenotype was observed in the dentate gyrus of acute and chronic treated 6, 12, 15 month APP/PS1 groups ($p<0.05$ and $p<0.01$). These results demonstrate that GLP1 analogue Liraglutide increases neurogenesis and has a potential to be developed as therapeutic drug for neurodegenerative disorders like Alzheimer's disease.

Title: Chronic liraglutide treatment prevents amyloid plaque deposition and memory impairment in APP/PS1 mice

Authors: *P. MCCLEAN, V. PARTHSARATHY, C. HOLSCHER
Neurosci. Res. Group, Univ. of Ulster, Coleraine, United Kingdom

Abstract: Recent research has demonstrated that type 2 diabetes is a risk factor in the development of Alzheimer's disease. The incretin hormone Glucagon-like peptide-1 (GLP-1) facilitates insulin signalling, and long-lasting analogues such as liraglutide (Victoza®) are on the market as treatment for diabetes. We reported previously that liraglutide treatment effectively improved cognitive function, reduced amyloid plaque deposition, inflammation, overall APP and amyloid oligomer levels and enhanced LTP when injected for two months in 7 months old APP*swe*/PS1 ΔE9 (APP/PS1) mice. Liraglutide also reversed disease progression when injected at 14 months of age and significantly improved recognition and spatial memory, reduced beta amyloid plaque load, total APP and aggregated beta amyloid levels and inflammation after 2 months treatment. As APP levels were reduced, the current study was designed in order to elucidate if liraglutide could exert a protective effect when administered *before* plaque deposition and associated behavioural impairments are present in the APP/PS1 model. Accordingly, 8 week old APP/PS1 mice were injected with liraglutide (25nm/kg bw) or saline (0.9%w/v) for 8 months. Wild-type mice injected with saline (0.9%w/v) served as a control. After 8 months treatment (aged 10 months), both wild-type saline ($p=0.0040$) and liraglutide treated APP/PS1 groups ($p=0.0016$) had excellent object recognition performance, while APP/PS1 saline treated mice failed to discriminate novel and familiar objects (0.0679, ns). APP/PS1 liraglutide-treated mice also performed significantly better in the water maze probe trial ($p<0.001$) and reversal probe trial ($p<0.01$) than APP/PS1 saline-treated mice. LTP in APP/PS1 liraglutide-treated mice was also enhanced compared with both wild-type saline ($p=0.0238$) and APP/PS1 saline ($p=0.0186$) groups. Overall plaque load and inflammation will be assessed, alongside total brain APP and beta-amyloid oligomer level. Further results will be disclosed at the meeting. The overall results obtained with liraglutide show an impressive array of neuroprotective effects which make it a promising candidate for the treatment of AD.

Title: Rosiglitazone-dependent rescue of synaptic deficits in dentate granule cells of Tg2576 mice

Authors: *F. LAEZZA[1,2,3], M. NENOV[4,2], C. HERNANDEZ[4,2,3], K. DINELEY[4,2,3]

Abstract: Alzheimer’s disease (AD) is the most common type of the debilitating dementias, and hippocampal dysfunction underlies the cognitive deficits which are a hallmark of AD. New memories are formed and transiently stored in the hippocampus through plasticity of synaptic circuits, and synaptic deficits in AD are observed in conjunction with cognitive impairment. New evidence indicates a link between insulin signaling, cognitive enhancement and AD. In support of that, the insulin-sensitizing drug Rosiglitazone (RSG), a potent and selective agonist of the peroxisome proliferator-activated receptor gamma (PPARgamma), ameliorates cognitive deficits in AD mouse models and has been evaluated in clinical trials on AD patients with some success. Yet, the cellular mechanisms by which RSG improves cognitive function are unknown.
To begin deciphering the cellular mechanisms underlying PPARgamma-agonism in AD, we have examined the synaptic activity of granule neurons in the dentate gyrus, a critical area for learning and memory following RSG treatment in 9 months old Tg2576, a treatment known to effectively enhance cognition in this AD model. We found that the frequency of spontaneous excitatory postsynaptic currents (sEPSCs) recorded in dentate granule neurons from untreated 9 months old Tg2576 mice was dramatically increased compared to WT control, and restored to normal levels by RSG. In contrast, sEPSC amplitude was unchanged in both WT control and RSG-treated Tg2576 mice. Our data suggest that one of the modalities by which RSG normalized cognition in Tg2576 (and possibly AD brain) is achieved through normalization of synaptic transmission in the dentate gyrus.

Title: Acute or long term Liraglutide treatment is protective against the effects of systemically induced inflammation stimulated by LPS administration both in peripheral tissues and in the brain

Authors: *K. HUNTER, S.-L. MCELREAVEY, R. GUNNING, C. HOLSCHER
Life and Hlth. Sci., Univ. of Ulster, Coleraine, United Kingdom

Abstract: It has become apparent in the last number of years that neuroinflammation plays a major role in the pathophysiology of Alzheimer's Disease (AD). Both post mortem brain tissue from AD patients and studies using transgenic animal models have provided evidence that activated microglia and astrocytes, as well as activated complement and release of cytokines and chemokines, are all associated with the progression of AD. Furthermore, systemic inflammation such as infection or other inflammatory episodes, cause further deterioration in the cognition and memory of AD patients. Our previous studies have shown that the anti-diabetic drug Liraglutide possesses anti-inflammatory properties, such as reduction of activated microglia, with an associated reduction in beta-amyloid and an improvement in cognition and memory in APP/PS1 mice. Therefore, in the present study we aim to elucidate more fully the role of Liraglutide on cytokine levels in the brain, serum and spleen and on markers of inflammation and oxidative stress in the brain, such as IBA1, GFAP, iNOS and 8Oxoguanine, when administered with the endotoxin LPS. When administered acutely with 1 or 2 doses of LPS Liraglutide demonstrated clear anti-inflammatory effects in the periphery, as the levels of a number of proinflammatory cytokines in the spleen were significantly reduced (*P<0.05 to **P<0.01). Immunohistological analysis also revealed anti-inflammatory effects of Liraglutide in the brain. IBA1 and GFAP expression was reduced (****P<00001 and P<0.01) as well as expression of iNOS and 8Oxoguanine (****P<0.0001 and **P<0.01 to ****P<0.0001). In a longer term study APP/PS1 mice that received 3 weeks Liraglutide treatment were protected from any further damaging inflammatory effects from an LPS challenge. These animals performed as well as controls in the object recognition task and Morris water maze. Further results of this study such as LTP analysis, immunohistological analysis and MSD multispot analysis of cytokine levels in peripheral tissues and the brain are currently underway.

Abstract: Background: In Alzheimer's disease (AD) there is a shift in the trophic to anti-trophic balance of amyloid precursor protein (APP) processing toward the anti-trophic state, reducing sAPPα relative to Aβ species. Restoration of this balance may be essential to reverse the underlying mechanisms that lead to AD.
Methods: High-throughput screening (HTS) of a clinical compound library in 7W CHO cells expressing huAPPwt was used to identify "hits" increasing sAPPα.The hit F03 was re-tested in primary neuronal culture, and was then determined to be brain-permeable. A 28 day study (0.5 mg/kg/day) was performed using J20 PDAPP (huAPP $^{Swe/Ind}$) mice and non-transgenic (NTg) littermates (N=6) ; working memory and hyperactivity were assessed using the Novel Object Recognition (NOR) task. A 56 day study (0.5 mg/Kg/day) was performed using J20 and NTg mice (N=12) wherein spatial memory was tested by Morris Water Maze (MWM). A study with I5 huAPPwt mice (10mg/Kg/day) was also performed. Biochemical analysis included sAPPα (AlphaLISA, Perkin-Elmer) and Aβ1-40 and 1-42 (ELISA, Invitrogen) of either separate or combined hippocampal (Hip) and entorhinal cortical (ECx) tissue samples.
Results: F03 increased sAPPα by 30% in HTS and by 25% in primary culture. In the 28 day J20 study, hyperactivity was reduced to NTg levels by the end of the study. Novelty preference was increased in F03-treated J20s to NTg levels at 14 days and was even higher than non-transgenic controls at 28 days. sAPPα was significantly increased and Aβ1-40 significantly decreased in the ECx, and Aβ1-42 significantly decreased in both the Hip and ECx. In the 56 day study, F03-treated mice spent more time in the target quadrant and crossed the platform area more often in the hidden and reversal probes, significantly so in the latter. sAPPα significantly increased and Aβ1-42 significantly decreased in the combined Hip+ECx tissue samples.
Conclusions: Our iterative hierarchical screening method to identify "switching" compounds that restore the trophic balance in AD - increasing sAPPα relative to Aβ - identified F03 as a hit. It was found to be effective at the human-equivalent dose of 0.5 mg/Kg/day, has an excellent

safety profile, and is suitable for immediate transition to human clinical trials as a candidate therapeutic for mild cognitive impairment (MCI) and AD.

Title: Efficacy of a novel proneurogenic neuroprotective small molecule, P7C3, in the 3xTg-AD transgenic mouse model of Alzheimer’s disease.

Authors: *G. L. BECKER[1], S. R. ALLY[1], A. BURKET[1], P. J. HUNTINGTON[1], W. KNOBBE[1], D. M. MCDANIEL[1], J. NAIDOO[2], J. M. READY[2], S. L. MCKNIGHT[2], A. A. PIEPER[1]

Abstract: Alzheimer’s disease (AD) is a debilitating age-related neurodegenerative disorder characterized by progressive cognitive impairment, the accumulation of β-amyloid (Aβ) peptide and neurofibrillary tangles in the hippocampus and cortex, along with neuronal loss. There are several medications (e.g. cholinesterase inhibitors) approved by the Food and Drug Administration to treat cognitive impairments associated with AD; however, none of these delay the onset or halt the progression of AD. The hippocampus is one of the earliest and most severely afflicted regions of the brain in AD. Therapeutic strategies to protect neurons from dying in AD, or to augment hippocampal functioning, might provide new treatment options for patients. We have discovered a novel small molecule with potent proneurogenic and neuroprotective properties, termed P7C3, which readily crosses the blood-brain-barrier and can be safely administered to rodents for an extended period of time. Extended treatment with P7C3 effectively restores hippocampal neurogenesis, structure and synaptic functioning in mice deficient for neurogenesis (npas3-/-mice), and also blocks apoptotic cell death and cognitive decline in aged rats. We are now evaluating the efficacy of administration of P7C3 to 3xTg-AD

mice, a rodent model of AD that with age exhibits decreased hippocampal neurogenesis and neuronal cell loss, as well as plaque and tangle pathology associated with synaptic dysfunction. P7C3 was administered twice daily (10 mg/kg) from 3 months of age until 12 months of age and mice received Morris water maze (MWM) testing every 3 months. This extended treatment with P7C3 increased performance in the MWM for 3xTg-AD mice, relative to vehicle-treated 3xTg-AD mice. Furthermore, P7C3-treated 3xTg-AD mice did not exhibit the same weight loss as compared to vehicle-treated mice. We are currently evaluating the effects of more potent analogs of P7C3 on these and other outcome measures as well. Our hope is that this work will provide a basis for the development of new pharmacologic treatment strategies for patients with AD.

Title: Ketogenic diet improves motor performance but not cognition in mouse models of Alzheimer’s disease pathology

Authors: *M. L. BROWNLOW[1], L. BENNER[2], A. JOLY[1], D. D'AGOSTINO[1], M. GORDON[1], D. MORGAN[1,2]

Abstract: Like many disorders, dietary manipulations are increasingly viewed as possible approaches to treating neurodegenerative diseases. Recent studies suggest that Alzheimer’s disease (AD) patients present an energy imbalance with brain hypometabolism and/or mitochondrial deficits. Ketogenic diets (KD), widely investigated in the treatment and prevention of seizures, have been suggested to bypass metabolic deficits present in AD brain by providing ketone bodies as an alternative fuel. We investigated the effects of a ketogenic diet on two mouse models of AD. Five months old APP/PS1 and Tg4510 mice were kept on either a KD or a control (NIH-31) diet for 3 months and then submitted to a battery of behavioral tests. Body weight and food intake were monitored throughout the study and blood was collected at 4 weeks and at the end of the study for ketone and glucose assessments. Both APP/PS1 and Tg4510 mice

weigh less than nontransgenic mice, yet, surprisingly, have elevated food intake. The ketogenic diet does not affect these differences in body weight or food consumption. We found that both mouse models of AD presented hyperactivity, measured by both open field and the y-maze tests, compared to non transgenic age-matched controls and that this effect was not prevented by KD. Mice kept on KD performed significantly better on an endurance trial in the rotarod compared to mice on the control diet independent of genotype. Only a genotype effect was observed in the radial arm water maze test with no significant differences between diets. Tissue was collected at the end of behavioral testing and additional analysis of amyloid, tau and microglial markers are ongoing. These initial data suggest that the metabolic rate of the transgenic mice is considerably greater than the nontransgenic mice and that ketogenic diet may play an important role in enhancing motor performance in mice.

Title: Potassium 2-(1-hydroxypentyl)-benzoate promotes synaptic transmission in animal models of Alzheimer’s disease

Authors: *X. WANG, P. LI, W. WANG, S. XU, Z. LIU, L. WANG, Y. PENG
Inst. Materia Med., Beijing, China

Abstract: Potassium 2-(1-hydroxypentyl)-benzoate (*dl*-PHPB), a novel compound that was demonstrated to have neuronal protective effects and was approved for phase I clinic trial of ischemia stroke. It has been found to improve learning and memory deficits in our preliminary studies. The aim of the present study was to further investigate the ameliorative effects and the possible synaptic mechanisms of *dl*-PHPB on cognitive capability.
The effects of *dl*-PHPB on synaptic plasticity were observed through long-term potentiation (LTP) recording *in vivo* in Wistar rats and in APP/PS1 transgenic mice. *Dl*-PHPB did not affect basal synaptic transmission. But, it significantly enhanced the HFS-induced LTP when preinjected (in CSF) for 30 min and the potentiation persisted for at least 60 min. This

potentiation was prevented by the blockade of postsynaptic NMDA receptors. Application of NMDA receptor antagonist D-APV (150μM in CSF) i.c.v 40min before HFS could significantly suppress LTP. Furthermore, pre-injection of D-APV (150μM in CSF) 10min before *dl*-PHPB application completely prevented *dl*-PHPB induced LTP improvement. In addition, oral treatment of *dl*-PHPB could recess the LTP deficits induced by muscarinic inhibition (scopolamine i.p.) or $A\beta_{1-42}$ injection (cerebral ventricle). *Dl-PHPB* could also reverse the memory impairment performed in step-down passive avoidance task and improve LTP deficits in 14 month old APP/PS1 mice.
The results demonstrated an important role of *dl*-PHPB in learning and memory improvement under pathophysiological conditions *in vivo* and explained a possible synaptic basis of its effects on cognitive amelioration. *Dl*-PHPB might be a potential drug candidate for the treatment of Alzheimer's disease.

Title: Targeting of peripheral monocytes by a nasal proteasome-based vaccine to induce Aβ clearance in an animal model of Alzheimer's disease

Authors: R. CIALIC[1], O. BUTOVSKY[1], *D. J. SELKOE[2], H. L. WEINER[2]
[1]Ctr. for Neurologic Dis., [2]Brigham & Women's Hosp, Boston, MA

Abstract: Alzheimer's disease (AD) is characterized by extracellular amyloid β-protein (Aβ) deposition (in neuritic plaques) and intraneuronal aggregates of phosphorylated tau protein (in neurofibrillary tangles). The growing evidence for the "*amyloid hypothesis*" of AD, which focuses on a key role for Aβ accumulation in initiating the pathogenic cascade, has led to intense efforts to develop Aβ reduction strategies. We previously found that nasal treatment of APP-Tg

mice with a proteasome-based adjuvant (Protollin) reduced Aβ deposits that co-localized with activated CD11b+ cells. In that study, Protollin was detected only in the periphery, which led us to propose a non-CNS effect of Protollin on Aβ burden mediated by peripheral monocytes. Thus, we hypothesized that the effect is mediated via activation of blood-derived monocytes, either via their infiltration into CNS and direct uptake of Aβ or indirectly by their induction of Aβ uptake by resident CNS microglia. To characterize the origin of the CD11b+ microglia present in the brain of Protollin-vaccinated APP-Tg mice, we generated chimeric mice by reconstitution of the BM of 20-month-old APP-Tg-mice with wild-type BM cells expressing GFP under the CX3CR1 promoter. Two months after this BM-transplantation, AD-chimera mice (age 22 mos) were treated intranasally with Protollin (1 µg/mouse) for 2 or 6 weeks. In addition, we used our novel microglia-specific antibodies to distinguish and characterize the phenotype of resident microglia, recruited monocytes and splenic monocytes in control and Protollin-treated APP-tg mice. We used Nanostring quantitative technology for 179 inflammation-related genes to profile the microglia and monocytes. We have found that nasal treatment of the AD-chimera mice with Protollin: 1) significantly reduced Aβ plaque levels accompanied by an increase in the numbers of recruited CD11b-GFP BM-derived monocytes having intracellular immunoreactivity for endogenous Aβ. CD11b was expressed by all GFP+ cells adjacent to residual Aβ plaques, but by hardly any of the non-GFP+ resident microglia; 2) activated splenic $Ly6C^{Hi}$ monocytes having increased expression of inflammation-related genes related to the M1 phenotype. Resident microglia were not affected by Protollin treatment. Thus, nasal treatment with proteasome-based adjuvants targets peripheral monocytes, modulates their pro-inflammatory M1 phenotype and induces their recruitment to Aβ-plaques in the brain of APP-tg mice to facilitate Aβ plaque clearance.

Care Syst., Palo Alto, CA

Abstract: The p75 neurotrophin receptor ($p75^{NTR}$) is one of a few receptors associated with multiple mechanisms specifically related to neuronal degeneration in Alzheimer's disease (AD). In earlier studies, crossing Thy-1 $hAPP^{Lond/Swe}$ ($APP^{L/S}$) mice with $p75^{NTR}$ mutant mice resulted in decreased neuritic degeneration and dystrophy (Knowles et al, JNS, 2009). Modulation of $p75^{NTR}$ function might therefore constitute an important therapeutic strategy. Previous *in vitro* studies demonstrated that a non-peptide small molecule, LM11A-31, binds to $p75^{NTR}$ and induces Akt signaling to promote hippocampal neuron survival (Massa et al 2006, JNS). Further, LM11A-31 prevented amyloid-β-induced degeneration and deleterious signaling in neuronal and hippocampal slice cultures (Yang, Knowles et al PLoS ONE, 2008).The present study assessed the effects of LM11A-31 on neuronal dysfunction and degeneration in $APP^{L/S}$ mice. Following oral administration, LM11A-31 was found to cross the blood brain barrier and reach brain concentrations known to provide neuroprotection *in vitro*. Once daily oral administration of LM11A-31 over a three month period prevented deficits in novel object recognition and Y-maze performance, without detectable toxic effects. While the number and size of basal forebrain cholinergic neurons were unaffected in mice expressing the $APP^{L/S}$ gene, they exhibit neuritic degeneration and dystrophy in basal forebrain cholinergic neurons and hippocampus. These pathologic changes were prevented by LM11A-31 without affecting amyloid levels. These findings indicate that $p75^{NTR}$ is an important therapeutic target for AD, and that LM11A-31 or its derivatives represent a class of compounds with potential applications as protective agents in neurodegenerative disease.

Title: Do metallothionein and its derivatives protect against Aβ toxicity by an LRP mediated mechanism?

Authors: *E. D. EATON[1], B. BENNETT[2], V. BEREZIN[3], R. CHUNG[2], A. WEST[2]
[1]Menzies Res. Inst. of Tasmania, Hobart, Australia; [2]Menzies Res. Inst. Tasmania, Hobart, Australia; [3]Inst. of Neurosci. and pharmacology, Copenhagen, Denmark

Abstract: Introduction
The metal binding protein metallothionein (MT) protects neurons against toxic agents including copper-bound amyloid-β (Cu-Aβ). With others, we have shown that this is primarily by a metal swap mechanism by which zinc bound by MT is exchanged for copper bound by Cu-Aβ. However, MTs are also known to bind to Lipoprotein Receptor-Related Protein (LRP) receptors including LRP1 and LRP2 thus promoting neuronal regenerative growth and survival. MT does not cross the blood brain barrier, and therefore peptide analogues derived from the MT sequence have been designed, termed emtins. We asked whether emtins also protect neurons against Cu-Aβ and if so, by which mechanism.
Method
Embryonic rat hippocampal neurons in primary culture were treated with Cu-Aβ (10μM) for 24 hours and neuronal viability tested by an Alamar Blue assay. The protective effects of MT, and the emtin variants emtinAc and emtinB were compared by co-incubation with Cu-Aβ. EmtinB action in the presence of the LRP inhibitor Receptor Associated Protein (RAP) (1μM) was also examined. The ability of emtin Ac and B to block the copper-mediated aggregation of Aβ into SDS insoluble aggregates was also examined by SDS-PAGE after 72 hours, and compared to the well characterised inhibitory action of native MT.
Results
Cu-Aβ treatment reduced neuronal viability to 53% (+/-1.0) compared to control, but co-incubation with emtinB (10μM and 25 μM) restored viability to 71% (+/- 2.0) and 82% (+/- 2.3) of control respectively. In contrast, emtinAc (10μM and 25 μM) increased cell viability from 67% (+/-9.3) to 79% (+/-7.5%) and 85% (+/-14.2%) respectively, but this was not significant. Inclusion of the LRP inhibitor RAP (1μM) significantly blocked the protective effect of emtinB (Plus RAP 76% +/-3.3, Minus RAP = 94% +/- 2.3). Neither EmtinAc nor emtinB (25μM) were

able to prevent the formation of insoluble Cu-Aβ during a 72 hour incubation, however MT (25μM) abolished the formation of insoluble Cu-Aβ, as assessed by SDS-PAGE.
Conclusion
The MT analogue emtinB protected cultured hippocampal neurons against Cu-Aβ toxicity and this action was blocked by an LRP receptor inhibitor. This is similar to the action of native MT, however we further showed that emtinB was not able to block copper-induced aggregation of Aβ, suggesting that it does not participate in a metal exchange mechanism. In contrast, the related MT analogue emtinAc was neither neuroprotective nor prevented Aβ aggregation. We are investigating the action of emtinB further in animal models of AD.

Title: Glutamine deprivation may contribute to neurodegenerative disease: Cell cycle reentry, reduced autophagy and altered mitochondrial function

Authors: *J. CHEN, K. HERRUP
Rutgers Univ., PISCATAWAY, NJ

Abstract: We have previously reported that glutamine acts as a neuroprotectant against DNA damage, beta-amyloid and H_2O_2-induced stress, and that neurons depend on both endogenous and exogenous glutamine for survival (Chen and Herrup, PLoS one, 2012). Here we report the results of our recent studies aimed at learning the pathways that may contribute to this protection. One key element is the effects of glutamine on autophagy. Normally, in untreated mature neurons
(DIV12-15), we find low amounts of LC3II, one index of the autophagic process. In mature neurons treated with H_2O_2, by contrast, we find marked increase of LC3II after an oxidative challenge. The involvement of glutamine in this process is seen through our observations that if glutamine was removed from the media before H_2O_2 treatment, then no increase of autophagy is induced. A second key pathway by which glutamine acts as a neuroprotectant is through its impact on mitochondrial function. Without glutamine, mitochondria form a long fused network

and this effect is seen in both primary hippocampal neurons and neuroblastoma cells. The strong suggestion of these findings is that adequate levels of glutamine are essential to guard the cell against deficiency of mitochondrial function. The final key element in the neuroprotection afforded by glutamine is the protection it offers against unscheduled neuronal cell cycle reentry. We find, as have others, that cells deprived of glutamine fail to complete a normal cell cycle. Again the effect is best seen when the cells are under stress. In the absence of glutamine, etoposide treatment caused a significant increase of the numbers of cyclin A -positive neuroblastoma (N2a) cells. Death follows quickly, but there was a telling absence of cyclin D1 expression. The suggestion is that a mitotic catastrophe is the proximal cause of death. Further glutamine deficiency in a second neuronal cell line, HT22 cells, leads to a significant increase in indices of cell death. Analysis of cell cycle kinetics suggests a mitotic catastrophe. In summary, glutamine is important for multiple cellular functions that are intimately related to diseases such as AD. Given that chronic inflammation is one of the central pathogenic features of AD and systemic inflammation causes dramatic loss of glutamine from brain, our data further suggest that glutamine deprivation may play a role in these diseases.

Title: Increasing activity of one mitochondrial enzyme is neuroprotective.

Authors: *G. E. GIBSON, H.-L. CHEN, H. XU
Neurol & Neurosci, Weill Cornell Med. College/Burke Med. Res. Inst., White Plains, NY

Abstract: Multiple reports indicate that the mitochondrial enzyme complex α-ketoglutarate dehydrogenase (KGDHC) is diminished in brains of patients that died with Alzheimer’s disease (AD). The decline is highly correlated to the clinical dementia rating scale of the patients before they died. The enzyme complex consists of three subunits (E1k, E2k and E3). *In vivo,* a reduction of E2k or E3 increases oxidative stress, reduces neurogenesis and makes the animals more sensitive to metabolic insults. *In vitro,* activities have also been reduced in vitro with

specific inhibitors, by shRNA or by using neurons from transgenic mice. The decline makes the cells more sensitive to oxidative insults and causes AD-like changes in calcium signaling. These experiments raise the possibility that increasing KGDHDC may be protective. Treatments known to be protective also increase KGDHC activity. For example, treatment with the vitamin E analogue trolox increases KGDHC by 120%. Increasing sirtuin activity by increasing NAD^+ with nicotinic acid riboside is protective. A six hour treatment with NR increased KGDHC activity by about 175%. Thus, we tested whether increasing just KGDHC could be neuroprotective. Neurons were transfected with AV expressing E1k. This increased E1k message four fold, protein level by 80% and increased KGDHC activity by 70%. The cells over-expressing KGDHC were resistant to hydrogen peroxide induced cell death. Thus, increasing KGDHC by either non-specific or specific means is neuroprotective.

Title: Intravenous immunoglobulin (IVIg) protects neuronal viability and synaptic markers in cultured degenerating primary hippocampal neurons

Authors: *J. A. BAILEY, B. RAY, D. K. LAHIRI
Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Alzheimer’s disease (AD) is characterized by deposition of plaques in the brain comprised primarily of the neurotoxic amyloid-β (Aβ) peptide. High levels of Aβ lead to abnormal synaptic pruning and neuron death which is thought to produce the disabling cognitive deficits seen in AD. Therefore, a promising treatment strategy for AD is to reduce levels of the Aβ peptide in the brain. We have shown previously that several neuroprotective compounds, including memantine (J Neurosci Res, 2010) and rivastigmine (J. Neurochem, 1010; PLoS One, 2011), can reduce Aβ levels. Since Aβ clearance may be slowed in AD, reduced production may be insufficient, so strategies to remove Aβ more directly are under investigation. These include several immunotherapy approaches, including intravenous immunoglobulin (IVIg). It has been

hypothesized that the circulating immunoglobulins from healthy donors will assist in clearing Aβ from the blood, and this treatment is currently in clinical trials. To investigate potential mechanisms of IVIg action on neuronal tissues, we cultured degenerating primary hippocampal neurons as previously described (Bailey and Lahiri, J Neurochem, 2010) and treated them with IVIg in order to assess its effects on neuronal viability and synaptic protein marker levels. Viability was determined by measuring levels of intracellular ATP, which increased significantly with IVIg treatment. Additionally, levels of the glycolytic enzyme lactate dehydrogenase (LDH) were measured. Cells treated with IVIg showed higher LDH levels in the lysates and lower LDH levels in media, indicating increased viability. Using Western immunoblotting of protein extracted from treated neuronal cells, we observed that neurodegeneration in the model reduced presynaptic markers SNAP-25 and synaptophysin to undetectable levels. Notably, treatment with IVIg increased levels of both markers. Similarly, the postsynaptic marker PSD95 was reduced to nearly undetectable levels with the vehicle, while increased significantly by IVIg treatment. However, the glial activation marker GFAP was not altered by IVIg treatment. Together, these results indicate that IVIg may act to improve survival of degenerating hippocampal neurons as well as protect synaptic connections between neurons. Further investigation of the effects of IVIg on secreted APP proteolysis products and other possible targets is ongoing. We are also testing the effects of IVIG in our recently developed human fetal brain cultures. This work provides a potential mechanism for cognitive improvements seen in early clinical trials of IVIg in AD patients.

Title: Rivastigmine promotes non-amyloidogenic α-secretase pathway in human fetal brain culture by increasing the levels of ADAM 9 and 10: Implications in Alzheimer’s disease (AD) therapeutics.

Authors: *B. RAY[1], J. A. BAILEY[2], N. CHOPRA[2], N. H. GREIG[4], K. SAMBAMURTI[5], D. K. LAHIRI[3]
[1]Indiana Univ., indianapolis, IN; [3]Psychiatry, [2]Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Natl. Inst. on Aging, Baltimore, MD; [5]Med. Univ. of South Carolina, Charleston, SC

Abstract: AD is characterized by deposition of amyloid β (Aβ) plaques, neuroinflammation and hyperphosphorylation of tau protein . Aβ is cleaved from the amyloid precursor protein (APP) by enzymatic actions of β-site APP cleaving enzyme (BACE-1) and γ secretase. APP is also processed by α-secretase to generate a p3 fragment and precludes Aβ production. Thus, promotion of the α-secretase pathway represents a rational therapeutic approach for drug development in AD. Rivastigmine is a cholinesterase inhibitor (ChEI) and one of the FDA-approved treatment options for mild-moderate AD. We have observed non-cholinergic, non-catalytic functions of ChEIs, including APP modulation (Greig et al, PNAS 2005; Lahiri et al JPET 2007. We have recently characterized rivastigmine's ability to increase levels of sAPPα in rat primary neuronal culture (Bailey et al 2011). To evaluate the mechanism, here we have treated human fetal brain (HFB) cultures with rivastigmine (100nM to 10 μM). Cultured cells were also treated with a non-selective ADAM inhibitor (TAPI2) alone or in combination with rivastigmine. Conditioned media (CM) samples and cell lysates (CL) were collected after the treatments and assayed for APP metabolites. Notably, rivastigmine treatment increased levels of sAPPα in HFB cultures. Concomitantly, rivastigmine decreased levels of sAPPβ, Aβ40 and Aβ42 vs controls by ELISA in CM samples. Further, rivastigmine significantly decreased levels of β-CTF vs control by ELISA in CL samples. Interestingly, these effects of rivastigmine were reversed by TAPI 2 co-treatment, suggesting rivastigmine's effects on ADAMs. Indeed, the rivastigmine-treated group showed increased levels of ADAM9 and ADAM10 vs controls by Western immunoblotting of CL samples. Levels of ADAM17 were unchanged between the treatment groups. Some of these findings were also observed in the hippocampal samples of APP-Tg mice treated with rivastigmine for three weeks. Taken together, our data suggest that rivastigmine can promote non-amyloidogenic α-secretase processing of APP by increasing levels of ADAM 9 and ADAM 10, resulting in decreased levels of Aβ. This novel property of rivastigmine warrants further studies in in vivo settings and can also be utilized in developing newer ChEIs and/or butyrylcholinesterase inhibitors in the treatment of AD.

Title: Regulation of APP processing using antibody fragments reduces stress induced toxicity in cell models of Alzheimer’s Disease

Authors: *V. R. SURYADI, S. EMADI, S. BODDAPATI, M. SIERKS
Arizona State Univ., Tempe, AZ

Abstract: Background: One of the most important neuropathological characteristics of Alzheimer’s disease is the aggregation and deposition of the protein beta-amyloid. Beta-amyloid is produced by proteolytic processing of the Amyloid Precursor Protein (APP). Production of beta-amyloid from APP is increased when cells are subject to stress since both APP and beta-secretase are upregulated by stress. An increased beta-amyloid level promotes aggregation of beta-amyloid into toxic species which cause an increase in reactive oxygen species (ROS), caspase-3 activity and a decrease in cell viability. Therefore reducing beta-amyloid generation is a promising method to control cell damage following stress. We have isolated a recombinant antibody fragment, iBSec1, which selectively blocks beta-secretase processing of APP by binding the APP substrate as opposed to blocking the enzyme active site. Here we show that iBSec1, when added extracellularly to mammalian cells overexpressing APP, reduces stress induced toxicity.
Methods: Different mammalian cells expressing APP treated with different concentrations of hydrogen peroxide to induce stress. Cells were also simultaneously treated with different concentrations of iBSec1 to inhibit beta-secretase processing of APP. Differences in toxicity of cells treated with or without iBSec1 were assayed by measuring changes in levels of ROS, Caspase 3 and mitochondrial health (XTT).
Results: Addition of hydrogen peroxide to cells showed a concentration dependent increase in ROS and Caspase 3 activity and a decrease in cell viability as determined by XTT. The increase in stress induced toxicity caused by addition of hydrogen peroxide was dramatically decreased by simultaneously treating the cells with iBSec1 to block the increase in beta-amyloid levels resulting from the upregulation of APP and beta-secretase.
Conclusions: Cellular stress increases ROS generation, Caspase-3 activity and decreases cell viability. Levels of beta-amyloid increase in cells following stress due to the upregulation of APP and beta-secretase activity, resulting in the formation of toxic aggregate species. Here we show that we can selectively control proteolytic processing of APP to inhibit beta-amyloid generation and reduce stress induced toxicity in cell models of AD. Since stress also upregulates APP and beta-secretase levels in healthy neurons, tailoring APP processing away from beta-amyloid generation may be an effective way to reduce stress induced toxicity in healthy neurons as well.

Title: Determining the mechanism of gamma-secretase modulators

Authors: C. J. CRUMP[1], D. S. JOHNSON[3], K. R. BALES[3], *Y. LI[2]
[1]Mem. Sloan -Kettering Cancer Ctr., New York City, NY; [2]Mem. Sloan -Kettering Cancer Ctr., NEW YORK, NY; [3]Pfizer Worldwide Res. and Develop., Groton, CT

Abstract: One of the major hallmarks of Alzheimer's disease is senile plaques, which are composed of amyloid beta peptides. These peptides are derived from the amyloid precursor protein (APP) after sequential processing by β- and γ-secretase. The two most predominant forms of amyloid beta peptides are Aβ40 and Aβ42, which are 40 or 42 amino acids long. The more hydrophobic longer peptides are thought to be the toxic and detrimental form. Mutations in APP or γ-secretase cause the rarer autosomal dominant form of Alzheimer's disease. These mutations result in an increase in the ratio of Aβ42 to Aβ40 peptides. Therefore, γ-secretase inhibition has been considered as a potential therapeutic mechanism to slow or prevent disease progression. However, γ-secretase activity is required for the processing of many transmembrane proteins in addition to APP, including activation of the notch pathway, which is essential for cell fate determination. Therefore, emphasis has now turned towards the development of γ-secretase modulators (GSMs), which not only prefer the APP substrate over Notch, but also specifically abrogate Aβ42 production over Aβ40 production. We have developed GSM based photo-labile probes for investigating the mechanism of action of these therapeutically promising small molecules. We have identified presenilin-1, the catalytic component of γ-secretase, as a target of GSMs. Furthermore, using active site based photo-probes we are investigating GSM-induced conformational changes in the active site of γ-secretase upon binding.

Title: The regulation of neuronal cell fate and neurogenesis by MSCs in Alzhimer`s Disease

Authors: *H. PARK, S. OH, H. KIM
Neurol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Alzhimer`s Disease (AD) is a progressive neurodegenerative disease that result in neuronal death and exacerbation of cognitive functions. Neurogenesis occurs in the subventricular zone (SVZ) of lateral ventricles, and in the subgranular zone (SGZ) of the dentate gyrus (DG) of the hippocampus. Although the neurogenesis mechanism is impaired in AD, it remains unclear. Bone morphogenetic proteins (BMPs) and its antagonist Noggin affect differentiation in the neural progenitor cells (NPCs) of adult brain. In particular, it is known that BMP4, the member of the BMPs family, induce glial differentiation of NPCs. But Noggin inhibits these mechanism and induce neuronal differentiation. The role for noggin in expasion and differentiation of NPCs has been debated. Because noggin is not the only factor inhibiting differentiation of BMP4-exposed NPC. Also, Wnt/β-catenin signaling regulates neuronal differentiation of NPCs. These signaling is activated by moving into nucleus β-catenin. In this study, We identified that β-catenin level is decreased, while BMP4 level is increased in the NPCs of AD brain. And exogenous application of mesenchymal stem cells (MSCs) increased noggin and β-catenin level. When Noggin is released by MSCs, β-catenin and BMP4 levels completely reversed. We thought that β-catenin promotes neuronal differentiation and induces activation of BMP4. Also, glial differentiation caused by expression of BMP4 is inhibited by noggin, which means neuronal differentiation. We progressed our experiment in vitro and in vivo. In vitro, we showed expression levels of BMP4, noggin, and β-catenin with RT-PCR and immunocytochemistry (ICC) and intracerebroventricular infusions of Ab into C57/BL6 mice triggered the brain of AD patient in vivo, so we measured exprssion level of neurogenesis by perfusion. These results suggest that noggin and β-catenin secreted by MSCs regulates neurogenesis while inhibiting BMP4. Thus, we demonstrate that noggin and β-catenin signaling is a key component of neurogenesis.

Title: Suspected limited efficacy of γ-secretase modulators

Authors: *N. KAKUDA[1], K. AKAZAWA[2], H. HATSUTA[3], S. MURAYAMA[3], Y. IHARA[1]
[1]Doshisha Univ., Kizugawa City / Kyoto, Japan; [2]Niigata Univ., Niigata, Japan; [3]Tokyo Metropolitan Inst. of Gerontology, Tokyo, Japan

Abstract: γ-Secretase modulator-like effect is found in the brains affected by mild cognitive impairment (MCI) and sporadic Alzheimer's disease (AD) brains. Due to this alteration in the activity, both levels of Aβ42 and Aβ43 in the cerebrospinal fluid (CSF) are profoundly decreased in MCI/AD. To compensate these decreases, CSF Aβ38 and Aβ40 are increased, and nevertheless Aβ42/43 seem to slowly progressively accumulate in the brain. Aβ38/42 and Aβ40/43 are distinct product/precursor pairs, and Aβ38/42 vs Aβ40/43 ratio plots clearly divided MCI/AD subjects and controls (Kakuda et al, 2012). This γ-secretase self-modulating seems to be planned to prevent further accumulation of Aβ42 and Aβ43 in the brain. We asked when this alteration would occur in the brain? Raft-associated γ-secretase activities prepared from autopsied brains in various Braak senile plaque (SP) stages were quantified. As a result, γ-secretase self-modulation was obvious in the stage of amyloid deposition, decades prior to clinically overt AD stage. Although stage A brains showed similar γ-secretase activity as controls, γ-secretase self-modulating seems to be related to the extent of amyloid-deposition in the brain.
We thus pointed out that the efficacy of Aβ42-lowering γ-modulator could be minimal in sporadic MCI/AD patients, as modulation of γ-secretase already occurs in amyloid-bearing brains. We also measured modulator-treated raft-associated γ-secretase activities in sporadic AD and control brains. GSM-1, a NSAIDs-derived Aβ42-lowering modulator, profoundly lowered Aβ42 and increased Aβ38 in the γ-secretase assay system. GSM-1 treated AD γ-secretase showed a similar trend but only to much less extent compared with control. Thus, we claim that the true efficacy of γ-secretase modulator should be evaluated in amyloid-bearing and γ-secretase-modulating brains.

Title: Tau antibody uptake into neurons strongly correlates with degree of tau pathology and is primarily receptor-mediated via low affinity Fcγ receptors.

Authors: *E. E. CONGDON[1], A. BOUTAJANGOUT[1,2], H. B. R. SAIT[1], E. M. SIGURDSSON[1,2]
[1]Dept. of Physiol. and Neurosci., [2]Dept. of Psychiatry, New York Univ. Sch. of Med., New York, NY

Abstract: Active and passive tau immunotherapy has been shown by us and more recently by others to be effective in animal models. In addition, we have previously reported that tau antibodies are able to enter into neurons and co-localize with intracellular tau aggregates within the endosomal/lysosomal pathway. However, the mechanism of uptake remained to be determined.
To this end, we have administered I^{125}-labeled tau antibodies into brain slice cultures prepared from transgenic (htau/PS1 and 3xTg) and wild type mice over 15 months of age. Slices were evenly distributed among the treatment groups, thus allowing each animal to serve as its own control. Following treatment, slices were washed with acidified buffer and subsequently several times with ice cold reaction buffer to minimize signal from extracellular binding of the antibodies.
To determine if antibody uptake is saturable, slices from htau/PS1 mice were incubated at 37°C with increasing concentrations (0.01-10 ug/ml) of I^{125}-labeled 4E6G7, a monoclonal tau antibody that we generated against the pSer396/404 epitope. Its uptake was rapid (< 1 h) which fits with our prior findings, and saturable between 5 and 10 ug/ml. Furthermore, incubating the sections

with a ten-fold excess of unlabeled mouse IgG resulted in 41% reduction in radioactivity ($p = 0.04$).
As receptor endocytosis is temperature-dependent, additional slices were incubated with I^{125}-4E6G7 for 1 hour at 4°C. Lowering the temperature produced a 63% decrease in radioactivity relative to slices at 37°C ($p = 0.002$). Inhibition of phagocytosis at 37° led to a small but non-significant decrease in uptake, suggesting that most of the antibodies were being taken up into neurons. To clarify if antibody internalization is mediated by low affinity Fc gamma receptors, slices were incubated with 0.5ug/ml I^{125}-4E6G7 and increasing concentrations of an antibody that blocks these receptors (FcBlock ; anti CD16/CD32; 0.05-50 ug/ml). It resulted in a dose-dependent decrease in radioactivity (26-56%, $p = 0.11$-0.04), indicating involvement of these receptors in the uptake of the antibody.
Interestingly, uptake strongly correlated ($r = 0.88$, $p = 0.003$) with tau pathology as determined by immunoblotting with PHF-1 in all three mouse lines used. These results suggest that tau aggregates strongly influence receptor-mediated endocytosis of tau antibodies and/or their retention within affected neurons.
In summary, our findings show that antibody uptake into neurons strongly correlates with degree of tau pathology, and is primarily receptor-mediated via low affinity Fc gamma receptors.

Abstract: Alzheimer's disease is characterized by a progressive loss of memory as well as increases in amyloid-β (Aβ) plaques, neurofibrillary tangles, inflammation, and neurodegeneration. Mesenchymal stem cells (MSCs) would likely be effective in alleviating the symptoms of Alzheimer's disease; however an optimal location of transplantation has yet to be determined. The present study compared the efficacy of various routes of administration of MSCs in alleviating symptoms in the 5xFAD transgenic mouse model of Alzheimer's disease. 5xFAD positive mice (AD) received transplantations of a total of 800,000 MSCs via bilateral injections into the lateral ventricles (LV), the hippocampus (Hipp), or divided between said locations (LV-Hipp), and were compared to AD mice and wild-type littermates (WT) injected with vehicle. After a post-operative period, the mice underwent a series of behavioral tasks, and their brains were analyzed using either immunohistochemistry (IHC) to assess levels of Aβ42 (the most aggregative form of Aβ), inflammation, and neuron loss, or enzyme-linked immunosorbant assays (ELISA) to assess levels of Aβ42 and synaptophysin proteins. In addition to improving learning, results of IHC analysis indicated that the MSCs appeared to have decreased the levels of Aβ42-labeling specifically in the fornix of all groups, as well as in the hippocampus of the Hipp and LV-Hipp groups. There also appeared to be a decrease in inflammation in the fornix of the LV-Hipp group. Therefore, MSCs should be considered as a viable treatment for AD, especially when injected into the LV and Hipp, which appeared to lead to a decrease in Aβ42 and inflammation in surrounding regions.

Title: Efficacy and mechanisms of antibody-mediated clearance of tau aggregates in a brain slice model

Authors: *J. GU[1], E. M. SIGURDSSON[1,2]
[1]Dept. of Physiol. and Neurosci., [2]Dept. of Psychiatry, New York Univ. Sch. of Med., New York, NY

Abstract: Pathological tau proteins are hallmarks of Alzheimer's disease (AD) and other tauopathies. These aggregates are hyperphosphorylated and form neurofibrillary tangles, with at least some of these assemblies leading to neuronal dysfunction and death. In AD, tau lesions correlate better with cognitive decline than Aβ burden. Therefore, clearing tau aggregates may be more effective to ameliorate cognition. Our previous studies and more recently those of others have shown that both active and passive immunization targeting phospho-tau epitopes reduces tau pathology and prevents cognitive decline in transgenic (Tg) mice. We have since developed several monoclonal antibodies (mAbs) targeting key pathological epitopes of tau. To assess their efficacy to clear tau aggregates, we established an ex vivo brain slice model of tau pathology. Slices were obtained from pups of tau P301L Tg mice and cultured for up to 6 weeks. In control experiments, 60% increase of hyperphosphorylated tau (PHF1/total tau ratio) was detected on western blots of slices from 2 to 6 weeks in culture. In treatment studies, the mAbs (10 µg/ml) were added twice per week from 2 to 6 weeks. The two mAbs tested, 4E6G7 (targeting phospho-S396/404 epitope) and 6B2G12 (targeting non-phospho S396/404 epitope), significantly reduced hyperphosphorylated tau by 25% and 38%, respectively, compared to control ($p<0.05$). Additionally, 4E6G7 reduced the amount of sarkosyl-insoluble tau (PHF1) in the slices by 28% ($p<0.01$). Analysis of the effect of 6B2G12 on this fraction is underway. We also examined the cellular mechanisms of mAb-mediated clearance of tau pathology in slice cultures from 1 year old P301L mice, which have extensive tau pathology. Fluorescent labeled mAbs entered neurons and bound to tau aggregates after 2 hour incubation. Lesser uptake of mAbs was evident in microglia but not in astrocytes or oligodendrocytes. Within neurons, the mAbs were largely co-localized with markers of the endosomal/lysosomal pathway. Our prior studies in neuroblastoma cells overexpressing human tau did not reveal any antibody uptake, presumably because these cells did not have tau aggregates. Cell line models remain, however, ideal to study spread of extracellular tau and related interventions. Slice models are closer to in vivo conditions and allow studies of the cellular mechanisms of mAb-mediated clearance of tau aggregates, which likely include both neurons and microglia. In summary, the ex vivo brain slice model provides a useful tool for screening mAbs before in vivo studies, and provides a valuable insight into the cellular mechanisms involved in clearing these aggregates.

Title: The therapeutic effect of Huperzine A on Alzheimer's disease involves a novel mechanism on brain iron regulation

Authors: *Y. KE[1], X. HE[1], M. S. C. TAM[1], Z. M. QIAN[2]
[1]The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Third Military Med. Univ., Chongqing, China

Abstract: The accumulation and deposition of amyloid-β (Aβ) peptides in the brain is a pathological hallmark in Alzheimer's disease (AD). Recent studies suggest a role of brain iron accumulation in the pathogenesis of AD. Huperzine A (HupA), a new alkaloid isolated from the Chinese herb *Huperzia serrata*, is a potent and reversible inhibitor of acetylcholinesterase. HupA is neuroprotective and improves cognitive functions. In this study, we found that the beneficial effect of HupA is related to a novel action on brain iron regulation. APPsw/PS1dE9 transgenic AD mice were treated with HupA (0.1mg/kg, po, once per day) or saline. We found that HupA treatment reduced insoluble but not soluble Aβ levels and markedly ameliorated amyloid plaques formation in these animals at ninth month of age. These effects of HupA were reduced by feeding the animals with a high iron diet starting from the second month. In parallel, we found that HupA decreases iron content in the brain. This effect was probably related to the action of HupA in decreasing the expression of transferrin-receptor 1 (TfR1) leading to reduced transferrin-bound iron uptake into cultured neurons. Taken together, these results suggest that, in addition to facilitated cholinergic transmission and neuroprotection, regulation of iron metabolism is a novel target of HupA in its therapeutic action on dementia.

Title: Conditional knock out of GSK-3αdecreases Aβ amyloid deposition and prevents memory deficits in PDAPP mice

Authors: *L. MOLINA PORCEL, D. E. HURTADO, J. C. CARROLL, C. MACDONALD, A. K. ABOAGYE, J. Q. TROJANOWSKI, V. M.-Y. LEE
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Glycogen synthase kinase-3 (GSK-3) is linked to the pathogenesis of Alzheimer's disease, but the specific contributions of each of the GSK-3 α and β isoforms in plaque formation in vivo have not been clarified. In this study, we sought to elucidate the role of each GSK-3 isoform using a conditional knock out approach. We generated triple transgenic mice using the CaMKIIα-Cre (α-calcium/calmodulin-dependent protein kinase II-Cre) system to knock down *GSK-3*α in PDAPP$^{+/-}$ mice (GSK-3α cko;PDAPP), however we were not able to generate viable GSK-3β offspring that survived beyond 6 months of age. GSK-3α cko;PDAPP mice were aged to 17 months and compared to their GSK-3α wt;PDAPP control litter-mates. Behavioral, biochemical and histological techniques were employed to ascertain both neuropathological and cognitive changes. We observed a dramatic reduction of GSK-3α immunostaining and protein levels measured by western blot, with no effect on GSK-3β levels in GSK-3α cko brains. Moreover, GSK-3α knockdown showed a significant effect on reducing senile plaques and ameliorating memory deficits in 17 month old PDAPP mice. These findings highlight the potential importance of GSK-3α as a possible therapeutic target for ameliorating behavioral impairments linked to Alzheimer´s disease senile plaques.

Abstract: Introduction:The activation of Liver X Receptors(LXR) has become in an important target for treatment of Alzheimer disease (AD). LXR activation up-regulates apolipoprotein E (APOE) that promotes the proteolytic degradation of Aβ, reduces amyloid plaque pathology, neuroinflammation and improve memory inamyloid models of AD (APP and PS1 mutantions). However the capacity of LXR agonist to improve the pathological characteristics in the triple AD models (APP, PS-1 and tau mutations: 3xtg) that form neurofibrillary tangleremains unclear.Aims:to analyze the potential of activation of LXR to improve the cognitive behavior in 3xtg model of AD. Methodology: We used de LXR activator GW3965 in the 3xtg model of AD which replicates more closely pathologic characteristics of AD including plaques, tangles, and synaptic dysfunction. We used two groups of animals: Group 1, short-term (ST) treatment for 6 days (50mg/kg/day) in 24-months old mice; Group 2, long-term (LT) treatment for 12 weeks (33mg/kg/day) in 12-months old mice. Cognitive performance was evaluated by using hippocampal dependent spatial memory: Morris water maze. Initially, learning tests were performed for 5 days, two trials for day; retention test were performed 48 hour after learning test; and transference test were performed for 2 days, two trials for day, 24 hour after retention test. Results: LT Litermates animals perform significantly better than 3xtg mice on 5 days of trials

($p<0.001$: learning, retentionand transference), as untreated 3xtg mice did not show any significant decrease in escape of latency over 5 days of trials. When 3xtg mice were treated with LT GW3965 there was no significant difference with litermates in these tasks. ST GW3965 treated 3xtg mice perform significant better than untreated 3xtg mice on learning and 4x retention tests in 5 days of trials ($p<0.01$). Conclusion: Both ST and LT GW3965 treatment restored memory functions in the 3xtg of AD. Further studies are underway to analyze the molecular mechanism associated to these cognitive changes.

Title: Antioxidants from tart cherries and essential fatty acids as treatment for cognitive deficits in the 5xFAD mouse model of Alzheimer’s.

Authors: *T. J. REINKE[1], J. J. MATCHYNSKI[1], S. ABDELAZIM[1], S. A. LOWRANCE[1], J. ROSSIGNOL[2], G. L. DUNBAR[1,3]
[1]Neurosci. Program, [2]Col. of Med., Central Michigan Univ., Mount Pleasant, MI; [3]Field Neurosciences Inst., Saginaw, MI

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disorder characterized by progressive memory loss, anxiety and personality changes, deterioration of cognitive abilities, and eventual motor and language dysfunction. Pathologically, AD is characterized by high levels of inflammation and oxidative stress, as well as a buildup of diffuse neuritic amyloid-β (Aβ) plaques and neurofibrillary tangles (NFTs). Studies have shown that humans with diets high in antioxidants are associated with lower levels of AD. In addition, because the brain contains a high amount of lipids, it is subject to peroxidation. As such, essential fatty acids, such as omega-

3, 6, and 9, are likely to be beneficial as a prophylactic treatment. A new compound, that conveniently offers a rich supply of both antioxidants and essential fatty acids, is Cerise Total Body Rhythm© (TBR; Cerise Pharmaceuticals, Traverse City, MI). TBR is a combination 17 antioxidants from tart cherry extract combined with omega-3, 6, and 9 from fresh water fish oil and ultra emu/kalaya oil. In the present study, TBR or vehicle (methylcellulose) was administered to the 5xFAD male mouse model of AD and wild-type littermates for 3 weeks. The 5xFAD mouse model was derived from transgenic mice that co-express five familial AD mutations. This model has proven to be well-suited for this study, as the mice show accelerated plaque development and very high levels of cerebral Aβ. A battery of sensitive behavioral tasks was used to test the effects of TBR as well as to provide a comprehensive profile of potential cognitive and behavioral deficits that emerge in male 5xFADs. Testing included the water t-maze (to assess learning deficits), rotorod (to assess balance), elevated plus-maze (to measure anxiety), pre-pulse inhibition (to measure sensory functioning), clasping (the withdrawal of the limbs to the torso), and open field (to assess spontaneous motor activity) tasks. Immunohistochemistry (IHC) was utilized to assess the levels of Aβ42-labeling, inflammation as measured by CD11b-labeling, and mitochondrial dysfunction as measured by cytochrome oxidase in the brain. The major findings of the current study indicate that: (1) TBR, at 60 mg/kg, was tolerated well in both normal WT and 5xFAD mice when taken daily for a 3 week period; (2) treatment with TBR reduced learning deficits in 5xFAD mice; and (3) IHC results suggest TBR may reduce levels of oxidative stress and plaque formation within the brain. Overall, the present study demonstrates the potential of TBR as an adjunct treatment for AD, as well as justifies future research on its long-term effects.

Title: The effect of a novel small molecule p75NTR ligand on locus coeruleus degeneration and related psychiatric behaviors in a transgenic mouse model of Alzheimer’s disease

Authors: *T.-V. V. NGUYEN[1], L. SHEN[1], N. L. SAW[2], L. VANDER GRIEND[1], M. SHAMLOO[2], T. WYSS-CORAY[1,3], S. MASSA[4,5], F. M. LONGO[1]

Abstract: Psychiatric symptoms such as anxiety, depression, aggressive/submissive behavior, social withdrawal, and psychoses frequently occur in Alzheimer's disease (AD). Most pharmacological treatments for managing these symptoms include the use of drugs that result in further disruption of cognition. Noradrenergic neurons of the locus coeruleus (LC) contribute to the regulation of mood and behavioral states and in AD undergo significant degeneration. The p75 neurotrophin receptor ($p75^{NTR}$) regulates a number of degenerative signaling mechanisms relevant to AD and has been reported to be expressed by LC neurons. Previously, our group demonstrated that non-peptide, small molecule $p75^{NTR}$ ligands prevent basal forebrain and hippocampal degeneration and improve performance on a battery of cognitive tests (Y-maze, novel object recognition, contextual fear conditioning, and water maze) in an amyloid precursor protein mouse model of AD (Thy1-$hAPP^{Lond/Swe}$) (SFN 2011). In this study, we first confirmed the specificity of a $p75^{NTR}$ antibody by western blot analysis of mouse brain extracts. This antibody was then used to confirm significant expression of $p75^{NTR}$ by LC neurons in wild-type (wt) and transgenic (Tg) mice. We then compared the effects of a $p75^{NTR}$ ligand (L1) and vehicle on noradrenergic neuron degeneration and psychiatric-related behaviors using wt and Tg mice. Tyrosine hydroxylase immunohistochemistry combined with blinded, unbiased Stereoinvestigator and Neurolucida imaging analyses showed no change in LC noradrengeric neuron number or size in Tg mice but did reveal a significant degeneration of neurites. L1 administered by oral gavage once daily for 3 months beginning at age 3-4 months prevented LC neuritic degeneration. Using a panel of behavioral tests designed to model psychiatric endpoints, we established that Tg mice exhibited significant anxiety-like behavior in the light-dark transition test, the elevated plus maze, and the elevated zero maze; submissive behavior in the test tube dominance assay; social withdrawal in an automated social phenotyper; and a sensorimotor gating deficit in prepulse inhibition. We did not detect depression-like behavior in Tg mice using the forced swim and tail suspension tests. Administration of L1 significantly improved sociability and on-going studies indicate a strong trend towards reducing submissive behavior and a sensorimotor gating deficit. The ligand did not reduce anxiety-like behavior when tested on the elevated plus maze. These findings point to a role for small molecule $p75^{NTR}$ ligands in slowing or preventing LC degeneration with potential amelioration of certain behavioral disturbances in AD.

Title: Modulation of Aβ oligomers in the Tg2576 Alzheimer’s disease mouse model by a novel generic anti-oligomer specific antibody

Authors: *M. J. GUERRERO[1], D. L. CASTILLO-CARRANZA[2], C. A. LASAGNA-REEVES[2], S. KRISHNAMURTHY[2], K. DINELEY[2], G. R. JACKSON[2], R. KAYED[2]

Abstract: Amyloid oligomers have been implicated as the primary toxic species in the pathogenesis of a broad range of degenerative diseases, including Alzheimer’s disease (AD). We were able to mimic these intermediates in the form of conformationally constrained peptides. Here we used these oligomer mimics and generated the first generic mouse monoclonal anti-oligomer conformation specific antibody that we called F11. This antibody does not recognize monomer or fibrillar structures. Therefore, it is a valuable reagent to investigate the benefits of specific oligomer clearance in mouse models of AD by passive immunization. We used this novel antibody and evaluated the benefits of Aβ oligomer modulation in fourteen month old tg2576 transgenic mice that express full length amyloid precursor protein with Swedish point mutations. Three days prior to the injection, tg2576 mice were tested using a novel object recognition (NOR) test, then vaccinated intravenous (two weeks apart) with 30 μg of F11 antibody; control mice received injections with control antibody. Behavioral analysis showed significantly improved performance on the NOR test after immunization. Immunohistochemical and biochemical analyses on the brains extracted from these animals one week after the second injection showed a reduction of amyloid oligomers in the animals immunized with F11.
The benefits of oligomer clearance by passive immunization validate oligomers as a potential target for the development of disease-modifying immunotherapy to treat AD and other conformational diseases.

Title: Geniposide improves spatial learning, inhibits tau phosphorylation, and decreases apoptosis in streptozotocin-induced Alzheimer disease model

Authors: C. GAO[1], Y. Z. LIU[2], *J. M. DING[3], L. LI[1]
[1]Physiol., [2]Second Hosp., Shanxi Med. Univ., Taiyuan, China; [3]East Carolina Univ. Med. Schl, GREENVILLE, NC

Abstract: Alzheimer's disease (AD) is a debilitating neurodegenerative disorder without effective treatment. Despite intensive studies, the exact pathogenesis of AD remains unknown. However, recent studies suggest that intra-cerebral-ventricular (icv) injection of streptozotocin (STZ) can induce an insulin resistant brain state that may underlie the neural pathogenesis of sporadic AD. Systemic administration of STZ induces pancreatic β cell dysfunction; whereas STZ-icv impairs glucose metabolism and redox function in the brain, resulting in learning and memory deficit accompanied with elevated amyloid protein and tau protein phosphorylation that are characteristic of AD pathology. This led us to attempt to treat AD with therapeutic agents that are known to ameliorate diabetes. Our recent work demonstrated that prior treatment with Val^8-glucagon-like peptide-1 (GLP-1) could prevent STZ-induced learning impairment and tau phosphorylation in the rat brain (li *et al* 2012).
The Chinese herbal medicine genipin is known to relieve symptoms of type-2 diabetes. Since genipin is thought to act as a GLP-1 receptor agonist, we investigated the potential therapeutic effect of geniposide on STZ-induced AD rats. Our result, using sprague dawley rats (200 gram), showed that a single injection of geniposide (50 μM, 10 μ l) to the lateral ventricle prevented STZ-induced spatial learning deficit by about 40% and reduced tau phosphorylation by about 30% with Morris water maze test and immunocytochemical analysis, respectively. Hyperphosphorylation of tau protein plays an important role in the neurofibrillary tangle development, one of the distinctive AD pathological hallmarks in the postmortem brain. Tau

protein is phosphorylated by a host of kinases, including glycogen synthase kinase-3 (GSK3), a serine or threonine kinase. STZ is known to increase the activity of GSK3β. Our result with western blot analysis showed that geniposide treatment prevented STZ-induced GSK3β hyperactivity. In addition, ultrastructure analysis showed that geniposide decreased the presence of a unique electron density that is thought to be an indicator for early apoptosis.
There are 5 FDA-approved medicines currently used for the treatment of AD, tacrine, rivastigmine, galantamine, donepezil, and memantine, but none provide any indication for halting or delaying the progression of the disease. Our study with the water soluble and orally active monomer of Chinese herbal medicine genipin may lead to the development of a potentially novel therapeutic agent for the treatment of both sporadic and familial AD.

Title: Modulating cellular clearance as a potential treatment for Alzheimer’s disease

Authors: *V. A. POLITO, L. HONGMEI, B. WANG, A. BALLABIO, H. ZHENG
Room N710, Baylor Col. of Med., Houston, TX

Abstract: Cellular clearance is a fundamental process required by all cells in all species. Important physiological processes, such as aging, and pathological mechanisms, such as neurodegeneration, are strictly dependent on cellular clearance. In eukaryotes, most of the cellular clearing processes occur in a specialized organelle, the lysosome. This project is based on a recent discovery, of TFEB (Transcription Factor EB) gene, that is a master gene for lysosomal biogenesis that coordinates expression of lysosomal genes and genes involved in autophagy; this gene participates in macromolecules clearance, moreover lysosomal

enhancement as a cellular response to pathogenic accumulation has been observed in neurodegenerative disease. The specific goal of the project is the evaluation of the potential therapeutic effect of TFEB on Alzheimer's disease pathology; to address this question an AAV-mediated gene therapy approach has been used.
A mouse model for Aβ accumulation and plaque formation (5XFAD) and a mouse model for NFT formation (Tg4510) have been used. Groups of mice from both mouse models were treated at p0 and adult age with AAV2/9CMVTcFEB-HA viral vector and analyzed after 4 months. Our preliminary data show that TFEB has no therapeutics effect of Aβ pathology. TFEB has a potential therapeutic effect on NFT pathology and a specific effect on pTAU reflecting a decrease in the accumulation of NFT; moreover there was an improvement in the learning process as we observed through the Morris-water maze test.

Title: Stimulating endogenous neurogenesis as a mechanism for functional repair in degenerating brain.

Authors: *M. PRIOR[1], P. MAHER[2], D. SCHUBERT[2]
[1]Cell. Neurobio. Lab., Salk Inst. For Biol. Studies, La Jolla, ; [2]Cell. Neurobio. Lab., Salk Inst. For Biol. Studies, La Jolla, CA

Abstract: Decreased levels of neurogenesis occur with age and perhaps in neurodegenerative conditions. Drugs that halt the degenerating process still leave the brain with dramatically

reduced neuron numbers and damaged neural circuits. Transplanting stem cells may not be successful because the specialized microenvironment of the neurogenic niche may be toxic in diseased brain so that neural precursor cells (NPCs) may not survive to become mature neurons. Therefore it is necessary to both increase nerve cell numbers and create an environment that is neuroprotective and promotes nerve cell differentiation. This situation presents a unique opportunity for CNS drug discovery in which the therapeutic stimulation of neurogenesis might contribute to functional 'repair' of the degenerating brain by increasing levels of proliferative and differentiation signals, while at the same time protecting newborn cells from a toxic environment. Reduced brain plasticity, loss of memory and reduced neurogenesis could be preserved by manipulating the self-renewal, proliferation, migration, survival and differentiation of NPCs. We have used a novel drug discovery paradigm to select drug candidates for the treatment of neurodegenerative diseases that is based on drug efficacy in cell culture models of multiple, age-associated pathologies, including stimulation of neurogenesis and neuroprotection. This scheme has identified a potent, orally active compound, J147 that facilitates memory in normal rodents, prevents behavioral deficits and synaptic protein loss in Alzheimer’s Disease (AD) transgenic mice, and reverses cognitive loss in aged transgenic AD mice. J147 is also neurogenic in both very old and young mice and reduces the significant loss in dendritic spines that occurs with age. J147 induces progenitor cell division and differentiation of NPCs derived from human ES cells into more nerve-like cells. J147 also directly stimulates endogenous neurogenesis as demonstrated by a neurogenesis ablation experiment. The very potent neurotrophic and memory-enhancing activities of J147 are associated with the induction of BDNF, a growth factor that is reduced with age and in AD brain, that is required for cognitive function, and is implicated in neurogenesis. Results suggest that J147, which has the medicinal chemical properties of a good CNS drug, is a promising compound for promoting neurogenesis in the aged brain and potentially for restoration of neuronal populations in brains recovering from neurodegenerative disease.

Title: Locally induced Alzheimer’s disease in 3D microengineered neuronal cell cultures

Authors: *A. KUNZE[1,2], P. RENAUD[2]
[1]Bioengineering, UCLA, Los Angeles, CA; [2]Microengineering, EPFL, Lausanne, Switzerland

Abstract: Aggregations of hyper-phosphorylated tau proteins, called neurofibrillary tangles, are major features in Alzheimer diseased (AD) brains. Tau proteins are responsible for maintaining microtubules structures in axons and dendrites (neurites). Now, when tau gets hyper-phosphorylated, microtubules become unstable, leading into degeneration of the neurite network. The progression of neurofibrillary tangles follows specific patterns in AD brains; although these patterns have been reported, their prediction is unknown. To study mechanism based on hyper-phosphorylated tau in vitro, neuronal cells are commonly exposed to okadaic acid (OA), which inhibits protein phosphatase (P-1 and PP-2A). Today's neuronal cell culture methods, however, lack controlled local cell position, cell micro-environmental architecture and local protein modification. We present, therefore, a novel cell culture method that combines the generation of locally hyper-phosphorylated tau proteins with the formation of controllable 3D micropatterned cell hydrogel layers. Primary neurons were prepared from cerebral cortexes of Wistar rat brains at embryonic day 19 (E19) and gently mixed with a liquid hydrogel solution of agarose / alginate (0.5 % / 0.3 % w/v) at 37 °C. Cell-loaded and cell-free hydrogel solutions were injected into microfluidic devices, which form four laminar 3D hydrogel layers in a main channel. After gelation of hydrogel layers, primary neurons were cultured up to 8 days (8 DIV). Neurons were loaded into the 1st and 4th hydrogel layers, facilitating neurite outgrowth into cell-free hydrogel layers across a distance of 320 μm. Our microfluidic devices allow the formation of molecular gradients through the hydrogel layers. After neurite outgrowth, cell layers were locally exposed to an okadaic acid (OA) gradient of 0.3375 nM/μm for 1h at 37°C. Neural cell activity was determined using Fluo-4 loading and calcium imaging. We quantified aggregates of hyper-phosphorylated tau proteins by immunofluoresecent labelling of pS262 sites and z-stack confocal imaging. Our results showed 7.5 times higher portions of hyper-phosphorylated tau aggregates in the 1st cell layers (high OA concentrations), compared to neurons in the 4th layer (low OA concentrations). Neural cells in the 1st layer, furthermore, showed reduced calcium activity. Further studies using this microfluidic based cell culture method may reveal the underlying impact of the microenvironmental architecture on the propagation of AD in diseased brains.

Title: Characterization of abeta oligomers from alzheimer’s disease brain with braak stage v/vi individuals and their effects on membrane trafficking in hippocampal neurons with cogrx compounds

Authors: *C. REHAK, R. YURKO, N. IZZO, K. MOZZONI, C. SILKY, G. RISHTON, H. SAFFERSTEIN, H. SAFFERSTEIN, M. MILLER, C. JOHANSON, E. STOPA, S. CATALANO
Cognition Therapeut., Pittsburgh, PA

Abstract: Abeta 1-42 oligomers accumulate in the brains of patients with Mild Cognitive Impairment (MCI) and begin to disrupt the balance of associative and dissociative synaptic plasticity processes that underlie memory formation (Knobloch and Mansury ’08, Selkoe ‘08). Published reports describe biological activity and cognitive deficits induced by several species of Abeta 1-42 oligomers ranging from dimers to high molecular weight assemblies isolated or prepared from a variety of sources (Reed et al.,’11). We isolated Abeta species from hippocampus (N=3) or neocortex (N=5) from Alzheimer’s patients (Braak stage V/VI, <24 hours post-mortem, median age 79) or age-matched histologically normal individuals (Braak Stage I, < 24 hours post-mortem, median age 74) using detergent free conditions and measured relative sizes of Abeta species via non-denaturing Westerns. Tissue was homogenized in 1:7 (w/v) in detergent-free Tris-HCl buffer, ultra centrifuged then immunoprecipitated with high salt elution (Pierce Gentle Elution Buffer), then separated by Amicon 100kDa and 10kDa MWCO spin filters. The human hippocampal (N=3 AD, 3 normal) and cortical (N=5 AD, 5 normal) derived oligomers were visualized by non-denaturing Western blot and resulted in a wide range of oligomer sizes that varied substantially between individuals and tissue location. Neocortical Abeta species consisted of a continuous band from 100-250k, and well defined bands corresponding to monomer and dimer. The higher molecular weight band was seen in both AD and normal individuals but was 30.5% more intense in AD patients. Hippocampal Abeta species were more heterogeneous both between all individuals and between AD and normals as a group, and consisted of well-defined bands at 75-85 kDa and a higher molecular weight band centering on 250kDa. There were lower concentrations of monomer (AD, -34%, normal -45%) and dimer in hippocampal (AD, -20%, normal -34%) samples than in neocortical samples. All human oligomer species were potently bio-active on DIV 21 hippocampal neurons inhibiting membrane trafficking with an EC50 of 3.5 pM following only one hour of exposure. This supports previous findings that several Abeta species exhibit biological activity in memory-relevant contexts.

Title: Therapeutic potential of endogenous cholesterol metabolites in alzheimer's disease.

Authors: J. JUNG[1], T. B. LADD[1], A. R. PRICE[1], B. D. MOORE[1], Y. TANG[2], G. SHAPIRO[3], G. HOCHHAUS[2], T. E. GOLDE[1], *K. M. FELSENSTEIN[1]

Abstract: $A\beta_{42}$ accumulation is a key etiological trigger for Alzheimer's disease (AD) and its reduction remains a promising therapeutic target. The rate limiting enzymatic step in the formation of Aβ is catalyzed by gamma(γ)-secretase and its modulation is a target for therapeutic intervention. Small molecules, that selectively lower $A\beta_{42}$ have been identified and are referred to collectively as γ-secretase modulators (GSMs). Although GSMs appear to be mechanistically safe 'anti-amyloid' compounds, many potent GSMs suffer from non-mechanistic liabilities that limit their potential usefulness in clinical trials. Discovery of new GSM chemotypes without these liabilities would be enabling. Recent studies have shown that cholesterol, its oxidized metabolites, and other sterols, have complex effects on the processing of amyloid precursor protein (APP) to Aβ. However, little is known about numerous other endogenous cholesterol metabolites and their effects on Aβ production; therefore, we explored whether these metabolites could modulate Aβ production. We tested a collection (~200) of acidic oxysterols and related non-acidic oxysterols for their ability to alter $A\beta_{42}$ levels. We identified several endogenous oxysterol metabolites as potent GSMs with EC50s of ~200nM- 1μM for lowering $A\beta_{42}$. These compounds had the classic signature of GSMs; they not only lower $A\beta_{42}$ but increase shorter Aβ peptides, and are active in broken cell assays. Several of these oxysterols are produced in the brain; therefore, studies are currently in progress to establish whether these are endogenous modulators of $A\beta_{42}$ formation, by examining Aβ production in CYP knockout mice that regulate metabolism of these oxysterols. In addition we are currently testing whether exogenous administration of these sterols and/or novel analogs can selectively lower brain $A\beta_{42}$ levels. The data suggests that acidic oxysterols may function as endogenous GSMs and these sterols or synthetic analogs could be potential therapeutic candidates for the treatment or prevention of AD.

Title: Multimodal Neuroprotective Strategies for Alzheimer’s disease

Authors: G. ZHANG[1], E. V. BATRAKOVA[2], H. A. GELBARD[4], C. L. LOWETH[5], V. S. GOODFELLOW[5], T. KIYOTA[1], *H. E. GENDELMAN[3]

Abstract: The aggregation of amyloid-β (Aβ) affects glial activation and neurotoxic responses during Alzheimer’s disease (AD) is linked, in measure, to production of pro-inflammatory factors and reactive oxygen species (ROS) influencing neurodestructive activities. We posit that improved therapeutic outcomes can be achieved through halting multiple stages of disease pathobiology (combination targeting) and at the level of protein aggregation, inflammation and neuronal functions. To this end we analyzed combinations of antioxidants (catalase) to effect Aβ aggregation and oxidative stress; A2a, a novel mixed-lineage kinase 3 (MLK-3) inhibitor with potent anti-inflammatory antioxidant activities; and noncompetitive N-methyl-D-aspartate

(NMDA) receptor antagonist that effect GluN2A, 2B and 2D and neuronal excitotoxicity. The overarching goal is to inhibit excitotoxic neuronal injury and Aβ aggregation to improve therapeutic neuroprotection. First, catalase alone or captured in a nanoformulation inhibited high molecular weight aggregates or Aβ oligomers protected against neuronal cell death. Second, catalase decreased nitric oxide synthase 2 (NOS2) in expression in BV-2 microglial cells after interferon-γ and Aβ oligomer stimulation. Third, parallel results were observed with our MLK-3 inhibitor or A2a was observed in regards to inhibition of neuronal demise. Combined treatment with catalase and the MLK-3 inhibitor in BV-2 microglial cells showed significant inhibition of NOS2 expression beyond the effects of each of the drugs or proteins alone. These results suggest a more than additive effect of both catalase and MLK-3 inhibitor as a therapeutic strategy for AD. The role of NMDA receptor antagonists in these drug mixtures remains underway.

Title: HDAC6 inhibitor recovers amyloid beta-induced impairment of mitochondrial transport in hippocampal neurons

Authors: *H. CHOI[1], C. KIM[1], C. JANG[1], S. OH[2], N. JEON[2], I. MOOK-JUNG[1]
[1]Col. of Med., Seoul Natl. Univ., Chongro-Gu, Seoul, Korea, Republic of; [2]Sch. of Mechanical and Aerospace Engin., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The axonal transport of vesicles or organelles, which occurs along microtubules, is important for neuronal functions and survival. α-and β-tubulin, which make up the microtubules, are acetylated. The acetylated level of alpha tubulin is related to axonal transport. The disruption of axonal transport, especially mitochondrial transport, has been shown to be a factor in neurodegenerative diseases like Alzheimer’s disease (AD) and Huntington’s disease. Histone

deacetylase 6 (HDAC6), which can deacetylase α-tubulin, is also known to be increased in AD patients. Therefore, we examined how the acetylation of α-tubulin in the presence of Aβ affects axonal transport, including mitochondrial transport. We found Tubastatin A (TBA), an HDAC6 inhibitor, significantly restored Aβ-induced reduction of axonal transport, including the velocity and motility of mitochondria. Also, TBA enhanced the elongation of Aβ-induced fissioned mitochondria, implying the inhibition of HDAC6 may play a role in recovering impaired mitochondria from Aβ toxicity. In addition, the brains of 5XFAD mice, AD animal model, showed a reduction of acetylated α-tubulin. This study revealed that HDAC6 is important in the axonal transport of mitochondria. HDAC6 inhibition was shown to elevate acetylated α-tubulin levels, resulting in improved mitochondrial transport, as well as the elongation of the mitochondria that had been damaged by Aβ. As reduced axonal transport and increased mitochondrial fission are closely related to AD pathogenesis, occurring before the appearance of senile plaque, the inhibition of HDAC6 could be a candidate for therapeutic target for AD, especially in the early stage.

Title: Amyloid beta inhibits entorhinal cortex activity through the activation of GSK-3

Authors: B. ORDAZ, A. SOLIS-CISNEROS, H. BALLEZA-TAPIA, J. LOPEZ-GUERRERO, *F. PENA
Neurobiología del Desarrollo y Neurofisiología, Inst. de Neurobiología, UNAM, Mexico, Mexico

Abstract: The cognitive decline observed in Alzheimer Disease has been related to amyloid beta-induced disturbances in several oscillatory patterns generated in the forebrain, specially in

the hippocampus. However, little is known about the alterations in the entorhinal cortex produced by the amyloid beta peptide. Thus, we tested the effects of the acute application of amyloid beta on the network activity of the entorhinal cortex slices in vitro. Moreover, we also explored the biochemical mechanisms involved in this effect. Our results show that bath application of amyloid beta (10 nM) activates the glycogen synthase kinase 3 (GSK-3) and reduces the network activity in the entorhinal cortex. The reduction network activity by amyloid beta is blocked by inhibiting GSK-3 either with lithium or with SB 216763. Our results suggest that amyloid beta-induced inhibition of entorhinal cortex network activity involves GSK-3 activation, which may provide a molecular mechanism for amyloid beta-induced neural network disruption and support the use of GSK-3 inhibitors to treat Alzheimer Disease.

Title: Substrate-specific dual inhibition of β- and γ-secretases by peptides binding to C99

Authors: *S. FUNAMOTO[1], T. SASAKI[3], S. ISHIHARA[1], M. NOBUHARA[1], M. TAKAHASHI[2], N. KAKUDA[1], K. NISHIKAWA[2], Y. IHARA[1]
[1]Neuropathology, [2]Mol. Life Sci., Doshisha Univ., Kyotanabe / Kyoto, Japan; [3]Peptidream Inc., Tokyo, Japan

Abstract: γ-Secretase is a promiscuous aspartic protease that cleaves transmembrane domain of type I membrane proteins, suggesting that inhibition of γ-secretase activity to suppress Aβ production causes harmful side effects. Thus substrate-specific inhibition of γ-secretase still remains as an unsolved important issue to overcome Alzheimer’s disease. We previously found that a subset of anti-Aβ antibodies raised against N-terminus of human Aβ significantly inhibited Aβ production without interfering Notch S3 cleavage in CHAPSO solubilized γ-secretase assay and that those antibodies also suppressed β-cleavage of human APP-derived fragment in vitro β-secretase assay. Our results indicate that N-terminus of carboxyl terminal fragment of β-amyloid

precursor protein (C99) is a potential target for substrate-specific dual inhibition of β- and γ-cleavages. In this study, we selected a subset of Cys-rich peptides binding to N-terminus of C99 out of our peptide library generated by RAPID display system. Those peptides exhibited inhibition of Aβ production from the C99 substrate and negligible effect on Notch S3 cleavage in the γ-secretase assay system. In addition, those peptides inhibited β-cleavage of APP-derived fragment (633-685, numbering from APP751) without interfering cleavage of sialyltransferase 1 (st6gal1), one of β-secretase substrates, in the β-secretase assay system. To test whether those peptides suppress Aβ production even in cell-based assay, we treated the CHO cells overexpressing human APP, Notch and st6gal1 with each peptide. Interestingly, all of those peptides exhibited significant reduction of sAPPβ, C99 and Aβ productions, but no effect on st6gal1 and Notch S3 cleavages. Importantly, peptides with reverse sequence showed no influence on sAPPβ and Aβ productions and cleavages of st6gal and Notch. Our results strongly suggest that N-terminus of C99 substrate is a novel potential target for substrate-specific dual inhibition of β- and γ-cleavages and that generating small molecules that specifically bind to N-terminus of C99 would be a novel strategy for substrate-specific dual inhibition of β- and γ-secretases without affecting proteolysis of other substrates for anti-AD approaches.

Title: Caffeine blocks neuronal uptake of LDL-cholesterol

Authors: *X. CHEN, S. LI, L. HUI, N. H. GEIGER, J. D. GEIGER
Pharmacology, Physiol. & Therapeut., Univ. of North Dakota, Grand Forks, ND

Abstract: Elevated circulating LDL-cholesterol, as an extrinsic factor, has been robustly linked to the pathogenesis of sporadic Alzheimer’s disease (AD), the major form (95%) of AD for which no effective treatment is available. Our recent in vivo and in vitro studies demonstrated that circulating LDL-cholesterol enters brain parenchyma via a leaky blood-brain barrier and is internalized by neurons. Such up-taken LDL-cholesterol appear to contribute directly to the pathogenesis of AD by promoting amyloid precursor protein (APP) internalization and

disrupting neuronal endolysosome function, both of which contribute to overproduction of amyloid beta (Aβ), one of the major pathological factor in AD. Thus, blocking neuronal uptake of LDL-cholesterol could provide a novel therapeutic strategy against AD. Recent epidemiological and experimental data suggest that caffeine is protective against AD, but by poorly understood mechanisms. Here, we tested the hypothesis that caffeine blocks neuronal uptake of LDL-cholesterol via its actions on adenosine receptors. Using receptor-mediated endocytosis assays, immunoblotting, immunostaining, ELISA, and RNA interference methods we found in primary culture neurons that caffeine pretreatment concentration-dependently blocked LDL-cholesterol internalization. Using a pharmacological approach, we demonstrated that only adenosine A3 receptor antagonists mimicked caffeine's effects on neuronal uptake of LDL-cholesterol. Furthermore, knocking down adenosine A3 receptors with siRNA blocked LDL-cholesterol internalization. In addition, caffeine pretreatment increased surface protein levels of both LDL receptors and APP. Moreover, caffeine attenuated LDL-cholesterol induced overproduction of Aβ. Our findings suggest that caffeine exerts its protective effects against AD by blocking neuronal uptake of LDL-cholesterol, thus attenuating APP internalization and decreasing Aβ generation.

Title: Gamma-secretase inhibitors, but not gamma-secretase modulators, alter brain-derived neurotrophic factor trafficking and signaling

Authors: *A. M. WEISSMILLER[1], M. PEARN[1], P. NGUYEN[1], R. E. TANZI[2], S. L. WAGNER[1], W. C. MOBLEY[1], C. WU[1]
[1]UCSD, San Diego, CA; [2]Neurosci., Harvard Univ., Boston, MA

Abstract: The amyloid theory of Alzheimer's disease (AD) proposes that Aβ deposit leads to neuronal dysfunction and overall toxicity. An attractive strategy for AD treatment is to suppress Aβ production by targeting the secretases that cleave the amyloid precursor protein (APP) to give rise to Aβ. As such, gamma-secretase inhibitors (GSIs) have been developed to treat AD. However, clinical trials with GSIs had to be discontinued due to the worsening conditions of patients and significant undesired side effects, which may be due to excessive accumulation of the C-terminal fragments of APP, Notch and many other gamma-secretase substrates. In contrast to GSIs, gamma-secretase modulators (GSMs) modulate the processitivity of gamma secretase to decrease Aβ40/42 production, while increasing the smaller Aβ38 form. Furthermore, GSMs do not appear to cause accumulation of APP-CTFs and CTFs of other gamma secretase substrates. While many studies have documented the ability of both GSIs and GSMs to function in lowering Aβ levels, nearly any evidence exists on the ability of these compounds to improve neuronal functioning at the *in vitro* level. To investigate the effect of GSIs versus GSMs on neuronal functions at molecular and cellular level, we used two structurally different GSMs (NGX 97555 and sGSM41) and one GSI (BMS-299897) to treat both mixed primary cortical and hippocampal neurons. Specifically, we assessed if and how signaling and axonal trafficking of BDNF was impacted in GSI- versus GSM-treated neurons. We found that GSI treatment of rat E18 hippocampal neurons cultured in microfluidic compartmentalized chambers resulted in a 60% decrease in retrograde transport velocity of quantum-dot conjugated BDNF and a 25% increase in anterograde movement, indicating trafficking of neurotrophic signals is significantly impaired. We further show that in GSI-, but not GSM-treated mixed cortical cultures activation of ERK1/2 by BDNF is selectively inhibited. Finally we demonstrate that upon GSI treatment, Rab7-marked late endosomes were translocated from soma to processes, an event that may lead to premature inactivation of the BDNF signal. Using the two structurally different GSMs we show that they differ slightly in their effect on normal neuronal function in that sGSM41-treated neurons function similar to vehicle, while NGX 97555 shows slower retrograde transport velocity, normal overall signaling, and little or no impairment of the endocytic pathway. Our results thus provide evidence that GSMs may make a more optimal choice in anti-amyloid based drug therapies and offer a possible mechanism for the deleterious effects of GSIs on both human and mouse cognition.

Title: Molecular dynamics modeling of IDE reveals striking conformational changes involved in substrate binding and catalysis

Authors: T. R. CAULFIELD, *S. G. YOUNKIN, M. A. LEISSRING
Mayo Clin. Jacksonville, JACKSONVILLE, FL

Abstract: Insulin-degrading enzyme (IDE) has long been known to be the principal protease responsible for inactivating insulin and also avidly degrades the amyloid ß-protein (Aß) that accumulates abnormally in Alzheimer disease (AD) . IDE has a bipartite active site formed from portions of the N- and C-terminal halves of the protease (IDE-N and IDE-C). The two halves are bowl-shaped and are connected by a flexible linker, allowing them to adopt “open” and “closed” conformations. When in the closed state, IDE encapsulates a large, 13,000-cubic Angstrom internal chamber. Numerous crystal structures of human IDE have been solved, but all of these have captured the protease in the closed conformation. The crystal structure of a bactierial homolog of IDE, pitrilysin, captured the protease in only a partially open conformation. Here, we present the full transition from closed to open state in a catalytically active form of human IDE containing insulin within its internal chamber. Utilizing molecular dynamics (MD), we have investigated how IDE transitions from the closed to the open state over a time interval of 250 ns. We have also shown that the binding a novel inhibitor we developed, Ii1, acts by maintaining the protease in the closed conformation. The combined MD studies are >1 microsecond and confirm the effect of having an apo IDE enzyme versus substrate-bound enzyme versus substrate-bound enzyme plus inhibitor. Our open conformation for IDE reveals that the open state exhibits a unique tetra-domain architecture, resembling the opening of a flower. IDE-N and IDE-C first separate, then each half separates further into a total of four subdomains. The end result reveals a possible mode for binding substrates quickly and efficiently. In on-going studies, we are now probing the conformational dynamics of various mutants, including the heterodimeric form of human IDE.

Title: Measuring brain interstitial fluid Apolipoprotein E using *in vivo* microdialysis "MegaProbes"

Authors: *J. L. RESTIVO, D. K. VERGES, W. D. GOEBEL, J. M. BURCHETT, D. M. HOLTZMAN, J. R. CIRRITO
Neurol., Washington Univ., Saint Louis, MO

Abstract: Apolipoprotein E (apoE) is a significant risk factor for late-onset Alzheimer's disease, altering clearance of the amyloid-β peptide that forms plaques in the disease, as well as altering the plaque's tertiary structure. ApoE's normal role is to shuttle cholesterol between cells in the periphery and in the brain. Interestingly, apoE found within the CNS is typically generated within that compartment as opposed to coming from the periphery. In vivo the apoE protein is rarely found in its free 35 kiloDalton form; instead it is typically associated to lipids which make the lipoprotein, HDL-like particles have a hydrated diameter in the 6-20 nanometer range. ApoE particles are found within the cerebrospinal fluid, though they appear to be produced within the brain parenchyma and diffuse through the brain interstitial fluid (ISF) to reach that compartment. Understanding apoE dynamics and metabolism over time within the brain may be important for understanding cholesterol transport within the brain, as well as apoE's role in neurodegenerative diseases such as Alzheimer's disease. Small molecules, such as neurotransmitters and small peptides, within the brain ISF can be measured using in vivo microdialysis. Large proteins, however, are typically not amenable to this technology due to steric hindrance which prevents large molecules from readily diffusing across a semi-permeable membrane to enter the microdialysis probe. We have optimized conditions to use microdialysis probes with a 1,000 kiloDalton (1 megaDalton) semi-permeable membrane to recover ISF apoE within the brains of wildtype and APP/PS1 transgenic mice (AtmosLM probes, Eicom, USA). These probes utilize a unique pressure-equalizing system to reduce pressure that typically forms when using large-membrane microdialysis probes. The inlet into the probe is essentially open to atmosphere while the dialysis is run using a peristaltic pump that "pulls" artificial CSF through the

probe/membrane. ISF murine apoE is detectable every hour over several days via ELISA to measure levels as well as using native non-denaturing gel electrophoresis to determine lipid particle size.

Title: Beta-amyloid immunization with behavioral enrichment in a canine model of aging: Antibody titers and CSF Beta-amyloid

Authors: P. R. DAVIS[1], *A. L. S. DOWLING[1], G. GIANNINI[2], X. WANG[1], T. BECKETT[1], T. PLATT[1], K. RUDOLPH[2], C. ROYER[2], D. PAGANI[3], F. BRESCH[4], M. P. MURPHY[1], E. G. BARRETT[2], E. HEAD[1]
[1]Ctr. on Aging, Univ. of Kentucky, LEXINGTON, KY; [2]Lovelace Resp. Res. Inst., Albuquerque, NM; [3]dP & Associates, Georgetown, ON, Canada; [4]Metacog Testing Systems, New Westminster, BC, Canada

Abstract: Alzheimer’s disease (AD) is characterized by the cognitive decline of an individual and the presence of hallmark pathology, including senile plaques (SP) and neurofibrillary tangles. SPs contain β-amyloid protein (Aβ), resulting from cleavage of the amyloid precursor protein (APP). A number of therapeutic strategies being developed today are focused on reducing the production or deposition of Aβ in the brains of patients with AD. The canine model is useful for testing potential therapeutic agents. Canines produce APP that has 98% homology with human APP. In addition, canines naturally develop Aβ neuropathology and show cognitive decline with age, similar to AD patients. Recent studies have shown that active immunization for 2 years with fibrillar Aβ1-42 (IMM) in aged canines significantly decreased brain Aβ and maintained executive function, while other measures of cognition remained unchanged (Head et al., 2008). However, behavioral enrichment (BEH) improves cognition (Milgram et al 2005) without reducing brain Aβ (Pop et al., 2010). We hypothesized that IMM combined with BEH would provide larger cognitive benefits and reduce neuropathology to a greater extent, as

compared to either controls or individual IMM and BEH treatments alone.Aged beagles (10.5-13.6 y) were placed into one of four groups: controls with Alum adjuvant only, fibrillar Aβ1-42 + Alum vaccine, BEH with Alum, and combination treatment (IMM+BEH). Dogs receiving BEH were housed with a kennel mate, had novel play toys each week, and were taken for a 20 minute walk outdoors three times a week. At baseline, animals were given a series of learning tasks and a spatial memory task and matched into equivalent groups on the basis of cognitive test scores. Animals were treated for over 15 months. Fibrillar Aβ1-42 antibody titers in serum and Aβ levels cerebral spinal fluid were measured by ELISA. When compared to non-IMM groups over the first 6 months of the study, anti-Aβ1-42 IgG responses in IMM groups increased significantly ($F(2,64)=3.24$ $p=0.046$) and were maintained. No systematic effects on CSF Aβ1-42, Aβ1-40, or total Aβ have been observed in response to 12 months of treatment. On a test of spatial attention (landmark task), BEH dogs performed significantly better than IMM dogs ($t(16)=2.7$ $p=0.016$). Additional measures of cognition are being collected. Upon completion of the study, changes in brain Aβ, extent of neurogenesis, and growth factor levels will be measured using immunohistochemistry and western blot analysis.

Title: Role of adenosine A1 receptor in cholesterol-induced Alzheimer’s disease like pathology

Authors: *J. P. RANTHAM PRABHAKARA[1], G. FEIST[1], M. SCHRAG[2], J. GEIGER[1], O. GHRIBI[1]
[1]Univ. North Dakota Sch. of Med. and Hlth. Sci., GRAND FORKS, ND; [2]Dept. of Biochem. and Neurosurg. Ctr. for Research, Training and Educ., Loma Linda Univ., Loma Linda, CA

Abstract: Objective: Hypercholesterolemia is a risk factor for Alzheimer’s disease (AD) by increasing the production of β-amyloid (Aβ), accumulation of which is deleterious to neurons. However, the mechanisms by which hypercholesterolemia cause Aβ accumulation and

neurodegeneration are not well known. Data from our laboratory has demonstrated that feeding rabbit with a diet rich in cholesterol leads to Aβ accumulation and down regulation of the adenosine A1 receptor (A1R). However, the extent to which down-regulation of A1R contributes to AD pathology is not well known. In the present study we have incubated organotypic slices from hippocampus of adult rabbit brains with agonist and antagonist of A1R in the presence of Aβ25-35 and 27-hydroxycholesterol (27-OHC), a cholesterol metabolite that increases Aβ production.
Methods: Organotypic slices were treated with 1μM of the A1R agonist 2-Chloro-N6-cyclopentyladenosine (CCPA) or 1μM of the A1R antagonist 8-Cyclopentyl-1,3-dipropylxanthine (DPCPX) in the presence or absence of 10μM Aβ25-35 or 25μM 27-OHC. After 72 hours of treatment, samples were harvested for Western blot and confocal microscopy. The media was collected and supplemented with protease and phosphatase inhibitor and used for quantification of Aβ by ELISA.
Results: We have found that Aβ25-35 and 27-OHC increase Aβ levels. Aβ25-35 and 27-OHC also increase levels of amyloid precursor protein (APP) and β-secretase (BACE-1) and decreased the levels of soluble amyloid precursor protein (sAPPα). Aβ25-35 and 27-OHC also increased phosphorylated tau, endoplasmic reticulum (ER) stress, inflammation, reactive oxygen species and the pro-apoptotic Bax levels. Treatment with the A1R receptor agonist reversed the Aβ25-35 and 27-OHC-induced AD pathology. Treatment with the A1R antagonist did not affect Aβ25-35 and 27-OHC -induced AD pathology.
Conclusion: Our results suggest that agonist of A1R may protect against AD like pathology.

Title: Effects of Apolipoprotein E in insulin signaling pathway

Authors: M. LIM[1], *F. TSANG[3], B. WONG[2]
[1]Physiol., [2]Natl. Univ. of Singapore, Singapore, Singapore; [3]Cerebos Pacific Limited, Singapore, Singapore

Abstract: Although Apolipoprotein E (apoE) is highly expressed in the brain and liver its functions remain unclear. It is widely known that apoE deficiency causes atherosclerosis and cardiovascular disease (CVD). Patients with type II diabetes mellitus (T2DM) are found to have other complications such as atherosclerosis, CVD and Alzheimer's disease (AD). In recent studies, apoE level is also found to affect the removal of b-amyloid (Ab) in AD mouse models. Therefore, it is interesting to find out how apoE plays a role in the cellular and molecular level. In this study, we choose to examine the effects of apoE on the regulation of insulin signaling by comparing the ApoE knockout (KO) mice to the wild-type (WT) mice brain during aging. We found that in the absence of apoE, it could cause down-regulation of the insulin signaling pathway which leads to several physiological and pathological problems. By probing the main targets of the pathway, we found that KO mice have a lower amount of insulin receptor substrate 1 (IRS1) and the phosphorylation of the serine residues in comparison to WT counterparts. PI3K which is the downstream effector of the IRS is not affected by the upstream activity. Furthermore, the KO mice at 32weeks expressed a higher amount of phosphorylated AKT. GSK3B has a higher activity as there is less phosphorylation at Ser9 in KO mice. These findings provide an insight on how apoE affects insulin signaling pathway. There will be more studies and experiments to be carried out in near future to better understand the pathway especially with respect to conditions like T2DM and AD.

Title: The role of GSK in regulating DNA methylation of genomic DNA in Alzheimer's Disease

Authors: *K.-L. CHEN[1], W.-H. CHEN[2]
[1]Shih Kong Wu Ho-Su Mem. Hosp., New Taipei City, Taiwan; [2]Shih Kong Wu Ho-Su Mem. Hosp., Dept. of Neurol., Taipei, Taiwan

Abstract: Background: Glycogen synthase kinase-3 (Gsk-3) isoforms, Gsk-3alpha and Gsk-3beta, are constitutively active, largely inhibitory kinases involved in signal transduction. Underscoring their biological significance, altered Gsk-3 activity has been implicated in diabetes, Alzheimer disease, schizophrenia, and bipolar disorder.
In previous data, we had proved that that Abeta reduces global DNA methylation whilst increasing neprilysin (NEP) DNA methylation and further suppressing the NEP expression in mRNA and protein levels. Our previous results also support that Abeta induces epigenetic effects, implying that DNA methylation may be part of a vicious cycle involving the reduction in NEP expression along with a resultant increase in Abeta accumulation, and that Abeta may induce global DNA hypo-methylation. Epigenetic changes marked by DNA methylation have been proposed to play a role in age-related disease. This year, Popkie et al. had report that Phosphatidylinositol 3-Kinase (PI3K) Signaling via Glycogen Synthase Kinase-3 (Gsk-3) Regulates DNA Methylation.
Methods: We used the SH-SY5Y cells to study Aβ-GSK and GSK-DNA methylation relationship. On the other hand, the inhibitors of GSK, lithium ion, or GSK interfering RNA were used to reverse GSK and verify the relationship between methylation and GSK pathway.
Result: We had known Abeta-induced DNA methylation can cause brain cells aging and apoptosis. The cells' methylation occurred on Alzheimer's disease have a certain impact. The gene is methylated, the performance decline, indirectly caused by reduced degradation of Aβ, and so a vicious cycle that will result in the accumulation of Aβ and promote the generation of AD. According to the published papers, we proved that Aβ affect DNA methylation is through GSK pathway.
Discussion: Understanding the impact of Abeta physical mechanism of DNA methylation and we used demethylation agents or GSK inhibitors to prevent the accumulation of Abeta in cell line first. In the future, it will further test in mice in order to find new ways to treat AD.

Title: Copper induces LRP-1 degradation by interacting with cellular prion.

Authors: *R. DEANE, I. SINGH, T. KASPER, J. CISZEWSKI
Dept. of Neurosurg., Univ. of Rochester, Rochester, NY

Abstract: Alzheimer's disease (AD) is associated with the deposition of senile plaques containing aggregates of amyloid-β peptide (Aβ) bound to metal ions, such as copper (Cu), zinc, and iron, and other molecules such as cholesterol and apolipoprotein E. Of these metal ions, Cu avidly binds Aβ and facilitates its aggregation and toxicity. The low-density lipoprotein receptor-related protein-1(LRP1) is a receptor for Aβ clearance. LRP1 levels in brain endothelial cells (BEC) are down-regulated with ageing and in AD. However, the mechanism for this down-regulation is unclear. Since brain Cu levels are increased with aging we hypothesized that increased Cu accumulation in BEC caused the reduction in LRP1 levels. Mice (C57BL6) were treated with tracer levels of Cu via their drinking water for 3 months to enhance the accumulation of Cu in brain. In contrast to capillary-depleted brain, Cu concentrations in plasma and brain capillaries were significantly ($p<0.05$) greater in the Cu-dosed mice compared to vehicle treated mice. LRP1 levels in brain microvessels were lower ($p<0.05$) and brain Aβ40 and Aβ42 concentrations were higher in the copper-dosed mice compared to vehicle treatment. Using immunoprecipitation, we show that Cu caused prion-LRP1 interaction, and reduction of LRP1 levels in brain endothelial cells. Therefore, Cu binding to prion may contribute to the specific down-regulation of LRP1 levels in brain endothelial cells. Cu-induced down regulation of LRP1 levels may reduce Aβ clearance leading to the accumulation of potential toxic Aβ species in brain. Supported by AG029481to RD.

Title: A model of Alzheimer's disease using human induced pluripotent stem cell derived cortical neuron cultures, astroctyes and microglia: Development, characterization and therapeutic approaches

Authors: *S. WRIGHT, S. HUSSAIN, J. BRIGHT, B. COOPER, E. ROSE, L. NGUYEN, V. DANG, C. RAMOS, U. SHOUKAT-MUMTAZ, J. GARNES, M. GRSKOVIC, J. DIMOS, E. BEATTIE, N. STAGLIANO, I. GRISWOLD-PRENNER, S. IRION
iPierian, S SAN FRAN, CA

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disease and the 6th leading cause of death in the U.S. The histopathological hallmarks of the disease are extracellular amyloid-beta protein (Aβ) plaques and intracellular aggregates of tau protein, with the two acting in concert to destroy neurons, leading to a decline in memory function. Multi-transgenic mouse models are commonly used to mimic human disease and while these models have helped our understanding of AD, they have been less successful in identifying new treatments. The reprogramming of adult fibroblasts to create induced pluripotent stem cells (iPSCs), and the subsequent redifferentiation to cell types of interest, offers a unique opportunity to study human disease using actual patient material. We collected skin fibroblasts from over 50 AD patients and controls, including familial presenilin mutants (PSEN1 and PSEN2) and generated iPSC lines from 18 individuals by retroviral transduction. The predominant cell types affected in, or believed to affect disease, in AD patients are pyramidal cortical neurons, microglia, and astrocytes. Methods have been developed and rigorously substantiated that differentiate iPSC into each of these cell types. Each cell type is identified by staining of specific markers and gene expression, and then assayed for functional endpoints (e.g., electrophysiological activity of neurons, stimulation of cytokine production for astrocytes and microglia). We then compared cortical neurons derived from AD to healthy controls and can recapitulate several features of AD. Familial PSEN1 and PSEN2 AD cortical neurons produce an increased ratio of secreted Aβ42/Aβ40 compared to both healthy and sporadic AD neurons, just as is observed in familial PSEN AD patients. Both familial and sporadic AD neurons show elevated levels of a subset of the AD associated phospho-tau epitopes which are elevated in AD cortex. Interestingly, elevated levels of total tau are also found in both sporadic and familial AD cortical neurons compared to healthy controls. Elevated phospho-tau is reduced through inhibition of Aβ production using BACE or gamma secretase inhibitors. We are using the changes in phospho-tau as a read out of disease state and have developed assays to test compounds for effects on phospho-tau as a therapeutic approach. Importantly, in addition to studying neurons in isolation, iPSC technology allows us to apply a "systems approach" to AD, combining patient derived neurons with patient derived astrocytes and microglia. We have successfully established neuron-glia cocultures and are using these culture systems to study cell non-autonomous pathologies of AD.

Title: Identification of MT-038, a tissue selective LXR modulator that inhibits apoE secretion in human astrocytoma cells

Authors: C. MORDAUNT[1], J. SCHOTT[1], A. VARGAS[1], S. MAITRA[2], *N. V. PATEL[1]
[1]Biol. Sci., CSU - Fullerton, Fullerton, CA; [2]Chem., CSU - Fresno, Fresno, CA

Abstract: Apolipoprotein-E (apoE) synthesis and secretion by astrocytes has implications for Alzheimer's Disease (AD) by facilitating amyloid-β (Aβ) clearance from the brain. However, the hypofunctional apoE ε4 isoform can accelerate AD pathology in vivo by differentially modulating Aβ clearance. Liver X receptor (LXR) and its obligate heterodimer retinoid X receptor (RXR) are among the best know regulators of apoE in the brain. Thus, these nuclear receptors are considered desirable targets for AD therapeutics. The objective of this study was to identify a novel class of small molecule inhibitors of apoE production in astrocytes. CCF-STTG1 cells (human astrocytoma cell line) were treated with a library of synthetic compounds for 24 hours and medium was analyzed for apoE content by ELISA. Our initial screen uncovered triarylmethylamines as inhibitors of apoE production. One compound of interest, MT-038, reduced extracellular apoE by more than 50% with an IC50 of 2.7 µM. We further characterized the biological effects of MT-038 to identify its mechanism of action. Q-PCR experiments demonstrate that MT-038 effectively inhibits apoE mRNA expression in CCF-STTG1 cells stimulated with LXR ligands. Consistent with an LXR-dependent mechanism, MT-038 also reduced steady-state ATP-Binding Cassette Transporter 1 (ABCA1) mRNA levels by more than 80%. Similar effects were seen in H4 cells (human neuroglioma cell line), but not HepG2 (human liver carcinoma cell line), suggesting that these effects are cell-type specific. Luciferase transcriptional assays showed that MT-038 repressed ABCA1 promoter activity (IC50 = 138 nM) and antagonized promoter activation by synthetic LXR ligands (GW3965 and T1317) and endogenous LXR ligands (22R-hydroxycholesterol and 24S-hydroxycholesterol). Antagonism of LXR ligands was also observed in HEK cells co-transfected with a GAL4-responsive reporter and fusion constructs of the GAL4 DNA-binding domain linked to the ligand binding domain (LBD) of LXRα/β. MT-038 did not show any activity against a panel of other GAL4-nuclear receptor fusion constructs, suggesting its activity is specific to LXR among related nuclear receptors. Furthermore, MT-038 exhibited inverse agonist effects in a TR-FRET

cell-free biochemical assay, as it inhibited the constitutive interaction of LXR LBDs with co-activator peptides. Taken together, our results strongly suggest that MT-038 inhibits apoE production by modulating the activity of LXR, and thus may be an important chemical probe used to study AD based therapeutics.

Title: Receptor antagonists inhibit abeta oligomer-induced memory deficits.

Authors: *S. M. CATALANO, N. IZZO, C. REHAK, R. YURKO, K. MOZZONI, C. SILKY, G. LOOK, G. RISHTON, H. SAFFERSTEIN
Cognition Therapeutics, Inc., PITTSBURGH, PA

Abstract: Small molecules that rapidly block the negative effects of Abeta oligomers on the molecular mechanisms of synaptic plasticity underlying memory have the potential to be disease-modifying Alzheimer’s therapeutics. We have discovered first-in-class receptor antagonists that block the toxic effects of Abeta oligomers by binding with high affinity to CNS receptors. These molecules 1) pharmacologically compete with oligomers for access to receptors regulating membrane trafficking rate, 2) eliminate Abeta oligomer-induced abnormal membrane trafficking and synapse loss/regression without affecting normal trafficking or synapse number, 3) prevent Abeta oligomer-induced associative memory failure in an acute AD model (Abeta 1-42 oligomer injection in wild-type mouse brain) as measured by fear conditioning, 4) reverse memory failure in both genders of a transgenic animal model at nanomolar brain concentrations following shorter duration of treatment than previously published therapeutics, and 5) exhibit a high brain/plasma ratio following long term administration and no neurotoxicity or glial toxicity in vitro, and no behavioral toxicity in vivo. The receptor antagonist mechanism of action will allow the design of disease-modifying therapeutic clinical trials based on receptor occupancy at critical receptor binding sites together with cognitive outcome.

Title: H63D-HFE induces brain atrophy and cognitive impairment by reducing brain cholesterol and synaptic function: implications for Alzheimer Disease

Authors: *F. ALI-RAHMANI[1], S. LEE[2], P. S. GRIGSON[3], E. NEELY[2], C.-L. SCHENGRUND[4], J. R. CONNOR[2]
[2]Neurosurg., [3]Neural and behavioral sciences, [4]Biochem. and Mol. Biol., [1]Pennsylvania State Univ., HERSHEY, PA

Abstract: The H63D variant of the hemochromatosis (HFE) gene, associated with deregulation of iron homeostasis, has been implicated as a risk factor for Alzheimer disease (AD). Apolipoprotein epsilon 4 (APOE4), a known risk factor for AD, is associated with disruption of cholesterol metabolism. Recent studies showed that individuals with both the APOE4 allele and the H63D variant had a much greater risk and earlier onset of AD than individuals carrying either APOE4 allele or H63D variant of HFE alone. Our global hypothesis is that the altered cholesterol metabolism associated with expression of H63D-HFE leads to disruption of cellular cholesterol homeostasis which will ultimately impact fidelity of lipid raft-mediated signaling pathways. We investigated the effect(s) of H63D-HFE on expression of cholesterol, major lipid raft component, using SHSY5Y human neuroblastoma cells transfected to stably express either wild type WT- or H63D-HFE. Total cholesterol content was ~ 50% reduced in cells expressing H63D-HFE with concomitant increase in expression of cholesterol 24S hydroxylase (CYP46A1), an enzyme involved in cholesterol efflux. Depletion of cholesterol by exposing cells to simvastatin significantly decreased survival of H63D-HFE expressing cells compared to WT-HFE cells, suggesting a genotype-dependent response to statins. Consistent with in vitro studies,

H67D (homologous to human H63D) knock-in mice, showed a genotype and age dependent decline in brain cholesterol and changes in the expression of proteins regulating cholesterol metabolism. A significant reduction in cholesterol, decrease in brain synaptophysin and increase in caspase-3 were observed in the brains of 18 and 24 month old homozygous H67D mice. Performance on learning and memory tasks (novel object recognition and Barnes maze) revealed memory deficits in H67D-HFE mice relative to WT-HFE mice. Magnetic resonance imaging of mice brains at the age of 9 and 24 months showed reduction of brain volume in H67D-HFE mice. Combined these data indicate that H63D variant induces alterations in the expression of proteins involved in cholesterol efflux resulting in excessive loss of brain cholesterol and proteins regulating synaptic transmission, eventually causing neuronal loss, brain atrophy, and memory impairment. Further lowering of cholesterol via treatment with cholesterol lowering drugs can have detrimental effects for H63D carriers. Therefore, these data support the hypothesis that expression of H63D-HFE establishes a permissive cellular milieu for pathogenic processes, contributes to the disease process in AD by altering iron and cholesterol metabolism and impacts treatment response.

Title: Alzheimer’s risk genotypes in the APOE and TOMM40 genes are associated with faster ventricular expansion rates: An N=644 ADNI study

Authors: *B. GUTMAN[1], P. RAJAGOPALAN[2], A. TOGA[2], C. JACK[4], M. WEINER[5], P. THOMPSON[3]
[1]LONI - UCLA, Los Angeles, CA; [2]Neurol. - Lab. of Neuro Imaging, UCLA, Los Angeles, CA; [3]UCLA, Neurology - Laboratory of Neuro Imaging, CA; [4]Mayo Clin., Rochester, MN; [5]Dept. of Veteran Affairs Med. Center, UCSF, San Francisco, CA

Abstract: Introduction
The epsilon 4 allele of the apolipoprotein E gene (APOE4) is a well-established risk factor for Alzheimer's disease (AD). The 'G' allele of the SNP rs2075650, located in intron 2 of the *TOMM40* gene, is also a more recently discovered risk factor for AD. *TOMM40* lies close to the APOE gene on chromosome 19 and the two alleles are in linkage disequilibrium (they are correlated). Both alleles are associated with greater brain atrophy in carriers, specifically temporal lobe atrophy and ventricular expansion. However, so far, it is unknown how *APOE4* and *TOMM40* SNPs influence *rates* of ventricular expansion. This was tested in our study.
Methods
We used 644 of the 738 Caucasian subjects (187 controls, 317 with mild cognitive impairment, 187 with AD; mean age: 75·4±6·8 years) who received a brain MRI at 1.5 Tesla at both baseline and 1-year follow-up and were genotyped as part of the ADNI cohort. All 644 subjects had *APOE*4 genotype data; of these, 616 had rs2075650 genotype data. The following multiple regression model was fitted at each point on the ventriclular surface:
$y = \beta_0 + \beta_{Predictors} Predictors + \beta_{Confounders} Confounders + \varepsilon$
APOE4 and *TOMM40* were tested individually, each coded as 0,1,2 after adjusting for age, sex and diagnosis. After registering all ventricular models, we created 3D maps reflecting profiles of neurodegeneration (expansion) associated with the genotypes. Permutations tests were used to correct for multiple comparisons.
Results
Both *APOE*4 (Corrected *P*-value: Right-0.0004; Left <0.0004) and *TOMM*40 (Corrected *P*-value: Right-0.0008 Left-0.0036) risk alleles are significantly associated with accelerated rate of ventricular expansion. 3D statistical maps show the associations predominantly in the body and occipital horn, stronger on the right than the left.
Discussion
This is the first study to reveal a dynamic 3D pattern of ventricular expansion associated with carrying Alzheimer risk alleles in *APOE4* and *TOMM40* genes. These anatomical profiles may

help to empower drug trials using various biomarkers to evaluate efficacy of interventions for Alzheimer's Disease.

Title: Spatial acquisition learning is remarkably restored after intranasal administration of WGA-conjugated NU4 antibody in 5XFAD mice during early plaque stage

Authors: C. XIAO[1], F. J. DAVIS[1], K. VIOLA[2], P. LACOR[2], V. P. DRAVID[2], *N. B. CHAUHAN[1], W. L. KLEIN[2]
[1]Dept Pediatrics/Anat Cell Biol, Jesse Brown VA Med. Center; Univ. Illinois Chicago, CHICAGO, IL; [2]Northwestern Univ., Evanston, IL

Abstract: Alzheimer's disease (AD) is a devastating incurable disease currently afflicting >5 million Americans that awaits effective disease-modifying treatment(s). Recognition of synaptotoxic Aß oligomers (also known as ADDLs) as a seeding event and as a primary

therapeutic target in AD pathogenesis, is emerging. Our ongoing collaborative work has demonstrated that intracerebral immunization with oligomer-specific anti-ADDL antibody (NU4) more efficiently reversed synaptic and behavioral deficits in a transgenic model of AD, than the conventional anti-Aß antibody (SFN/ICAD 2008). Currently, we used intranasal (IN) route of delivery to bypass brain barrier (BBB) and systemic adversities for transfer of immunotherapeutics directly to the brain. Further advancement included the use Wheat Germ Agglutinin (WGA) as an efficient vehicle to enhance delivery of immunotherapeutics by facilitating endocytic active intraneuronal uptake while simultaneously promoting passive extraneuronal uptake of unconjugated candidate drug due to nasal mucosa-like properties of WGA. This investigation was undertaken to examine if intranasal passive immunization usinga 1:1 mixture of WGA-conjugated plus unconjugated NU4 (*w*NU4) will improve spatial acquisition learning in 5XFAD transgenic mice modeling AD, and if there exists any gender difference. 8 weeks old male and female 5XFAD transgenic mice (Tgs) were intranasally injected with *w*NU4 [(10µg/5ul/naris) X 2 = (20µg/20µl/mouse/day), twice/week, for 8 weeks]. Age-matched male and female Tg/Lt controls received equal amount of saline (10ul/naris) for 8 weeks. Spatial acquisition learning was evaluated by Morris water maze (MWM). Data were analyzed using RMNOVA, Tukey posthoc test. Results showed that there was no significant difference in the learning pattern of males or females, both among Lts or Tgs, with or without treatment. Baseline data prior to beginning immunization indicated that the spatial learning in 2-month-old Tgs was significantly impaired compared to 2-month-old Lts (↓42%, RMANOVA, Tukey posthoc test, $p<0.0001$), which remained impaired to almost the same level in the 4-month-old age-matched saline injected Tgs compared to the 4-month-old age-matched saline injected Lts (↓41%, RMANOVA, Tukey posthoc test, $p<0.0001$). Intranasal immunization with *w*NU4 significantly restored spatial acquisition learning compared to saline injected age-matched Tgs (↑35%, RMANOVA, Tukey posthoc test, $p<0.0001$). Conclusion: Intranasal immunization with *w*NU4 efficiently reversed spatial learning deficits in the 5XFAD mice at an early plaque stage without exhibiting any gender difference.

Title: Bin1 expression is altered in Alzheimer’s disease

Authors: *C. J. HOLLER, E. HEAD, M. P. MURPHY
Univ. of Kentucky, Lexington, KY

Abstract: Recent genome wide association studies (GWAS) have implicated bridging integrator 1 (amphiphysin 2, Bin1) as a late-onset Alzheimer’s disease susceptibility gene. Bin1 was originally discovered as MYC-interacting protein that functions as a tumor suppressor; however, it also plays a critical role in cellular lipid metabolism. There are at least 15 different isoforms of Bin1 known, with many being expressed in the brain including the longest isoform (isoform 1), which is brain-specific and localizes to axon initial segments and nodes of Ranvier. In the central nervous system, Bin1 interacts with proteins such as clatherin, dynamin, amphiphysin 1, synaptojanin, and endophilin, and may function as an adapter protein that regulates synaptic vesicle endocytosis. It is currently unknown what role Bin1 may play in Alzheimer’s disease. Our lab set out to determine the expression pattern of Bin1 in control and late-stage AD brain tissue. By western blot, we discovered that the largest form of Bin1 (brain-specific isoform 1) was significantly decreased in AD in four separate brain regions: hippocampus, inferior parietal cortex, inferior temporal cortex, and frontal cortex (BA9). In contrast, several smaller isoforms of Bin1 were significantly increased in AD tissue, resulting in no significant difference in total Bin1 between control and AD cases. In human neuroglioma (H4wt) cells, overexpression of brain-specific full-length Bin1 or ubiquitously expressed Bin1 isoform 9 lead to an accumulation of full-length APP and a corresponding decrease in CTFs and total Aβ. Knock-down of Bin1 (total) using shRNA constructs is ongoing and we hypothesize that a decrease in Bin1 will increase Aβ levels possibly through a disruption in endocytic trafficking, which is important for Aβ generation. In addition, using quantitative real-time PCR, we are analyzing the levels of the various Bin1 isoforms from AD and control brain tissue to determine if Bin1 splicing is altered in AD. Finally, we examined the localization of Bin1 in human control and AD cases using immunohistochemistry to determine if the location of Bin1 in axons and neuronal synapses is changed in AD. These experiments will be useful in determining if Bin1 plays a critical role in the development of Alzheimer’s disease and may implicate Bin1 as an important biomarker or therapeutic target for the disease.

Title: Amyloid-β endocytic trafficking and recycling: Implications for its degradation, aggregation and toxicity

Authors: *J. LI, T. KANEKIYO, G. BU
Neurosci., Mayo Clin. Jacksonville, Jacksonville, FL

Abstract: Alzheimer’s disease (AD) is the most common neurodegenerative disease and the leading cause of dementia in elderly. Accumulation of amyloid-β (Aβ) peptides in the brain leads to its aggregation and toxicity, and is a major pathogenic event for AD. Aβ is cleaved from amyloid precursor protein and secreted into extracellular space. A portion of secreted Aβ can be re-internalized and metabolized by neurons and glia. To assess Aβ endocytic trafficking and the underlying implications for Aβ toxicity, we examined the specific roles of several small GTPases that regulate various endocytic trafficking steps. While Rab5 and Rab7 regulate early and late endosomal trafficking, respectively, Rab11 is involved in endocytic recycling. We found that overexpression of Rab5 or Rab7 significantly increases cellular Aβ accumulation, in particular in the presence of lysosomal inhibitors, suggesting that Rab5/Rab7-mediated lysosomal trafficking and subsequent degradation are major trafficking events for neuronal Aβ. Expression of a Rab5 dominant-negative mutant, which blocks early endosomal trafficking, leads to increased cell-associated Aβ. Interestingly, a blockage of the Rab11-mediated recycling pathway with a constitutively-active mutant also significantly accelerates cellular Aβ accumulation. Apolipoprotein E (apoE) further accelerates neuronal Aβ uptake and lysosomal trafficking in a manner that depends on apoE isoforms with apoE3 more efficiently facilitates Aβ lysosomal trafficking and degradation than apoE4, a risk factor for AD. Finally, we found that impaired lysosomal degradation of Aβ leads to its intracellular accumulation and aggregation. Taken together, our results demonstrate that Rab5, Rab7 and Rab11 regulate endocytic trafficking of Aβ through the lysosomal degradation and recycling pathways. A disturbance of these endocytic

trafficking and metabolic pathways can lead to intracellular Aβ accumulation, aggregation, and toxicity.

Title: N-pyroglutamate Abeta oligomer toxicity and its prevention by inhibition of glutaminyl cyclases

Authors: *H. U. DEMUTH
Probiodrug AG, Halle (Saale), Germany

Abstract: Alzheimer's disease (AD) is characterized by neuron loss and neuroinflammation. Although N-truncated and in particular N-pyroglutamated Aβ-peptides (pEAβ) are known as prominent constituents of plaques in AD brain, their importance has been ignored for some time and pathways leading to their formation not understood. Because of their abundance, resistance to proteolysis and neurotoxicity, such N-terminally truncated and modified peptides can be potentially important for initiation of pathological cascades leading to AD. Our recent work uncovers, that the N-terminal pE-formation is catalyzed by glutaminyl cyclase (QC) in vivo. QC expression was found upregulated in the cortex of individuals with AD and correlated with the appearance of pE-modified Aβ. Oral applications of QC inhibitors resulted in reduced pE3Aβ42 burden, but surprisingly also to the attenuation of the 1.000fold higher amounts of total Aβ in transgenic models of AD. Besides showing a diminished plaque formation and gliosis, we found improved performance in context memory and spatial learning tests. These observations led to the hypothesis that pEAβ can seed Aβ oligomerization by self- and co-aggregation with other monomeric Aβ species. In recent in vitro, in situ and in vivo studies amounts of less than 10nM pE3Aβ42 generated cytotoxic oligomers which are over 20 fold more stable than oligomers of the classical full-length Aβ-peptides. Such mixed pE3Aβ42 oligomers propagate their toxic structure in a prion-like manner. Moreover, the neurotoxicity unfolds to be strictly tau-dependent in cell culture as well as in new animal models. There, specific neuronal expression of pEAβ provides in vivo evidence for profound pEAβ neurotoxicity and gliosis induction.
Based on these data, we launched a broad QC-inhibitor development program which has entered the regulatory drug testing phase 2010. A phase 1 single (SAD) and multiple ascending dose

(MAD) study of PQ912 in healthy volunteers has been conducted since spring 2011. PQ912 is a glutaminyl cyclase (QC) inhibitor for the treatment of AD and it is the first QC inhibitor to enter clinical development.
The phase 1 trials, conducted in Switzerland, demonstrated that PQ912 is safe and well tolerated after oral dosing. Dose-proportional pharmacokinetics and a strong pharmacokinetic and pharmacodynamics relationship based on QC inhibition were observed in plasma and cerebrospinal fluid. The combined SAD/MAD studies involved more than 120 volunteers in a blinded, placebo controlled randomized trial.

Title: The role of metalloproteases in neurodegeneration: Recent findings

Authors: F. BELLIA[1], G. GRASSO[2], *E. RIZZARELLI[3]
[1]Inst. of Biostructure and Bioimaging, CNR, Catania, Italy; [2]Chem. Sci., [3]Univ. of Catania, Catania, Italy

Abstract: Carnosinases belong to the M20 metalloprotease family and they are mainly studied as carnosine-degrading enzymes. In mammals, two isoforms have characterized: the serum-circulating form (CN1), secreted by brain cells into the cerebrospinal fluid [1] and the cytosolic isoform (‘tissue carnosinase’, CN2), a non-specific dipeptidase distributed in several human tissues and in the rodent brain [2]. The role in the homeostasis of carnosine, a multi-functional endogenous dipeptide [3], makes the impairment of these enzymes very dangerous for the health of humans and other mammals.
In recent years, CN1 has attracted the interest of many scientists because of its correlation with aging and neurological disorders. CN1 is essentially inactive in newborn and its activity gradually rise with the age [4]. Moreover, the extent of the enzyme activity depends on the cerebral areas and the enzyme activity was significantly higher in all brain regions of senescent rats compared with that in aged animals [5]. Reduced CN1 activity in serum has been reported in

patients with neurological disorders, such as dementia and Alzheimer's disease [6].
In our lab we have found CN1 is able to degrade A-beta (1-40). The CN1 activity towards the A-beta hydrolysis has been studied in vitro in the presence of potentially new activators, inhibitors or competitors, such as transition metal ions, endogenous carnosine-related compounds and synthetic derivatives of carnosine.

Title: Trafficking of exogenous macrophages to and within the brain

Authors: *A. F. CINTRON[1], A. F. CINTRON[2], E. HEUER,[2], R. NAIR[2], J. DOOYEMA[2], L. C. WALKER[2]

Abstract: The introduction of Aβ seeds into the peritoneal cavity induces cerebral Aβ deposition in APP-transgenic mice (Eisele et al., Science 330:980-2, 2010). To determine how the seeds are conveyed from periphery to brain, we have investigated two potential cellular mechanisms,

intraneuronal transport and transport by macrophages, based on studies suggesting that the interaction of these cell types may facilitate the neuroinvasion of prion disease (Heikenwalder et al., J Mol Neurosci 23:3-12, 2004). Using the retrograde tracer fluorogold, we confirmed that the dorsal motor nucleus of the vagus is labeled following intraperitoneal injection, with no obvious label elsewhere in the brain. Because peripherally seeded Aβ occurs in widespread regions of the forebrain of APP23 mice, particularly around blood vessels (Eisele et al., 2010), we next investigated the disposition of exogenous macrophages labeled with fluorescent nanobeads shortly after infusion into the tail vein. We found that the macrophages migrate primarily to systemic organs such as the spleen and liver, but that infrequent exogenous macrophages also are found within the brain. When exogenous, labeled macrophages are injected directly into the brain, they tend to collect around cerebral blood vessels. Presently, we are investigating the trafficking and pathogenicity of exogenous macrophages bearing aggregated Aβ seeds derived from Alzheimer brain extracts in APP/presenilin-transgenic mice. From this work, we hope to identify the cellular mechanisms by which proteopathic seeds spread from one region to another, and thereby propagate cerebral Aβ-amyloidosis. Title: Role of cholesterol, IFN-γ and IL-1β on APP metabolism in astrocytes

Authors: *M. E. ÁVILA-MUÑOZ[1], P. FERRERA[2], C. ARIAS[2]
[1]Medicina Genómica y Toxicología Ambiental, Inst. De Investigaciones Biomédicas, UNAM, México, Mexico; [2]Medicina Genómica y Toxicología Ambiental, Inst. de Investigaciones Biomédicas, UNAM, Mexico, Mexico

Abstract: The neuropathology of Alzheimer´s disease (AD) is characterized by the presence of extracellular senile plaques that are mainly composed of the β-amyloid peptide (Aβ). Marked by focal activation of microglia and astrocytes in the vicinity of amyloid plaques, AD-associated inflammation has been widely described by pathological examination of brain tissue from AD patients and transgenic mouse models. The resulting neuroinflammatory processes usually involve the release from activated glia of a number of potentially neurotoxic molecules including cytokines such as IFN-γ and IL-1β that are thought can increased the production of Aβ. Other important risk factor for the development of AD is the presence of high levels of cholesterol. Although multiple lines of evidence indicate a role for cholesterol in the modulation of the lipid membrane, environment in which the proteins (APP, BACE-1 and nicastrin) for the Aβ production in neurons are located, the exact mechanisms involved in the cholesterol-induced amyloidogenic APP processing remain largely unknown in the neurons and astrocytes. In this work we aimed at evaluating the role of proinflammatory cytokines (IFN-γ 20ng/ml and IL-1β 10ng/ml for 48hrs) under the modulation of the composition of the lipid membrane with the use of cholesterol in the production of Aβ by astrocytes. Primary cultures of astrocytes were used trough the study and by Western blot, we assessed: 1) the presence of APP, BACE-1 and nicastrin proteins in astrocytes, 2) the effect of cytokines in the levels of these proteins and in the Aβ production, 3) the role of cholesterol (25 and 50μM for 48hrs) in the levels of APP, BACE-1, nicastrin and Aβ, 4) the combined effect of cytokines and cholesterol in the modulation of the amyloidogenic APP pathway, 5) the activation of astrocytes, by detection of GFAP, under the stimulation of cytokines and cholesterol. Our results so far show the presence of APP, BACE-1 and nicastrin in astrocytes. Cytokines as well as cholesterol have the ability to increase levels of APP in astrocytes and at the same time increase the expression of GFAP, indicating the activation of these cells. Furthermore, treatment of cytokines together with cholesterol, changed the APP levels but in a non-additive fashion. These results suggest that astrocytes have the proteins required for the amyloidogenic pathway and that cytokines and cholesterol can regulate Aβ production modulating the levels of APP after astrocyte activation.

Title: Apolipoprotein E Isoform-specific effect in the PI3K/Akt and MAPKs pathway in CAD cells

Authors: *M. A. ORTIZ, D. ORDOÑEZ, L. MORALES, A. SANDOVAL, H. ARBOLEDA, G. ARBOLEDA
UNIVERSIDAD NACIONAL DE COLOMBIA, Bogotá. D.C, Colombia

Abstract: Introduction: Apolipoprotein E (APOE) carries cholesterol and other lipids present in the plasma and in the central nervous system and binds to APOE receptors in order to control lipid homeostasis. There are three *ApoE* alleles in humans (*ApoE* ε2, ε3 y ε4). Although ApoEε4 has been implicated as a risk factor in Alzheimer's disease, the molecular effects associated to ApoEε4 have not been fully described. Aim: to study the differential effect of APOE isoforms in the AKT-mTOR and MAPKs pathways. Materials and methods: we used a murine CNS catecholaminergic cell line (CAD) as a study model. Protein expression was evaluated by Western blot. Mitochondrial metabolism was measured by MTT assay. Results: LDLR, an APOE receptor, is expressed after two days of differentiation of CAD cells. When differentiated CAD cells were treated with APOEε4 we found an increase in MTT assay associated with an increase in the phosphorylation level of AKT(Ser 473), ERK 1-2 (Thr 202/Tyr 204) and P38 (Thr180/Tyr 182) compared to APOEε2 and ε3 treatments. Phosphorylation of mTOR (Ser2448) was higher in cells treated with APOEε3 and ε4, and significantly lowers in those exposed to APOEε2. GSK-3β protein expression and phosphorylation did not show significant difference between treatments. In addition, APOEε4 also causes an increase in the expression level of hexokinase. Conclusion: These results suggest that APOEε4 raises glucose and mitochondrial metabolism and a subsequently cellular stress response associated to activation of the P38 pathway (maybe associated to an increase production of ROS). Activation of AKT and ERK pathways could be a compensatory survival mechanism. The increase in mTOR phosphorylation observed in cells treated with APOEε4 suggests and inhibition of autophagy maybe associated to the high intracellular glucose levels.

Title: Regulation of the BACE1 gene promoter by the SP1 and STAT1/3 transcription factors: Identification of possible drug targets for Alzheimer's disease (AD) treatment

Authors: *D. K. LAHIRI, J. A. BAILEY, B. MALONEY
Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: The β-amyloid cleaving enzyme (BACE1) is the rate-limiting enzyme responsible for cleavage of the amyloid precursor protein in order to produce neurotoxic β-amyloid (Aβ), which accumulates into plaque found in AD affected brain. Our goal is to study the recently proposed gene-environment interaction model, the LEARn pathway, for AD etiology (Lahiri et al, 2009). Our interest has been to study mechanisms by which the gene encoding BACE1 is regulated, with the hypothesis that reducing the rate-limiting enzyme will reduce Aβ levels, ameliorate symptoms and slow progression of AD. To this end, our recent work has identified possible feedback regulation mechanisms by which Aβ might act, itself, as a transcription factor (TF) on the BACE1 promoter, as well as multiple predicted binding sites for other TF, such as SP1 and STAT1/3 (Maloney & Lahiri, 2011; Bailey et al, 2011). We have proposed that SP1 and STAT1/3 influence BACE1 levels by direct modification of transcription through its gene promoter. To test such potential regulation of the BACE1 promoter, we stably transfected PC12 cells with a luciferase-based reporter gene system under control of a 3.3kb fragment of the 5' regulatory region of the BACE1 gene. These cells were neuronally differentiated with NGF and treated with selective pharmacological inhibitors of SP1, STAT1 or STAT3 activity. The SP1 inhibitors tolfenamic acid (an anti-inflammatory) and mithramycin (an anti-neoplastic) both dose-dependently reduced BACE1 promoter activity in these cells. Likewise, the STAT1 inhibitor fludarabine (chemotherapy agent), and the STAT3 inhibitor Stattic, both reduced BACE1 promoter activity, but to a lesser degree than either of the SP1 inhibitors. These results have important implications for the development of pharmacological inhibitors of BACE1 activity. We previously found that SP1 and BACE1 mRNA levels corresponded across the lifespan in primates (Dosunmu et al, 2009). Notably, as per the LEARn model (Latent Early-Life Associated Regulation) , environmental factors, including metals and dietary factors, operate by interfering the interaction of methylated CpG clusters with binding proteins, such as SP1. We also have found an active Aβ-interacting domain (AβID) on the BACE promoter and additional AβIDs overlap SP1 sites within the 3.3kb promoter fragment. Currently, agents aimed at reducing BACE1 activity in the brain have focused on inhibition of the enzyme, however, our cumulative data suggest that additional upstream targets at the level of transcriptional regulation may also be effective and have the added benefit of an already established array of compounds that could be developed for this purpose.

Title: Lysosomal localization of insulin-degrading enzyme

Authors: S. O. ABDUL-HAY, M. H. CHEN, F. CHEN, M. MCBRIDE, *L. H. YOUNKIN, M. A. LEISSRING
Mayo Clin. Jacksonville, JACKSONVILLE, FL

Abstract: Insulin-degrading enzyme (IDE) is an atypical zinc-metallopeptidase responsible for the degradation of insulin, the amyloid β-protein (Aβ), and other intermediate-sized peptide substrates. The subcellular localization of IDE differs markedly from conventional zinc-metalloproteases, and the intracellular site(s) where IDE interacts with its substrates remains surprisingly ill-defined. IDE is well-known to be abundant in cytosol, secreted into the extracellular space, and targeted to mitochondria via alternative translation initiation, but the extent to which it is trafficked to other intracellular compartments is not as firmly established. IDE contains 3 residues at its extreme C-terminus (AKL), which had been believed to constitute a Type-I peroxisomal targeting sequence (PTS1). However, the complete PTS1 has recently been shown to involve adjacent residues, and bioinformatic analysis that included these residues failed to yield a strong prediction for the targeting of IDE to peroxisomes. To test this, we constructed a series of (non-mitochondrial) IDE expression constructs tagged with red fluorescent protein (DsRed) at the N-terminus and containing either the wild-type C-terminus (WT), a C-terminal V5 tag (V5), deletion of the 3 terminal residues (ΔAKL) or substitution of the 15 terminal residues with a well-established PTS1 (PTS1). None of these constructs colocalized with a genetically encoded peroxisomal marker, nor with markers for endosomes, endoplasmic reticulum, Golgi, nucleus or adiposomes. Unexpectedly, DsRed-IDE colocalized strongly with multiple lysosomal markers, a finding that was confirmed for untagged forms of IDE, as well. Significantly, in stable cell lines expressing DsRed-IDE, lysosomes appeared to be the principal site of localization, in contradistinction to transient cells, which showed a chiefly cytosolic localization. Fluorescently labeled recombinant IDE was readily internalized by cells and localized to lysosomes, suggesting that IDE may normally be trafficked to this compartment via

endocytosis of secreted IDE. Of note, exogenous application of recombinant IDE together with fluorescently tagged insulin and Aβ led to colocalization within lysosomes, suggesting that lysosomes may be an important intracellular site for degradation of peptide substrates. In sum, our study suggests that IDE is trafficked to lysosomes, but not peroxisomes, which may represent the locus of degradation of insulin, Aβ and other internalized substrates.

Title: Generation and characterization of a mouse model of Parkinson disease-related neurodegeneration by deletion of the lysosomal ATPase Atp13a2

Authors: *L. KETT, A. SUBRAMANIAN, W. T. DAUER
Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: An increasing number of genes have been associated with familial forms of Parkinson’s disease (PD). Improved understanding of the cellular functions of these genes is likely to elucidate pathways common to both familial and idiopathic forms of PD that are amenable to therapeutic targeting. Mutations in the ATP13A2 gene cause Kufor-Rakeb Disease (KRD), an autosomal recessive parkinsonian syndrome that also features supranuclear palsy, pyramidal signs, and dementia. ATP13A2 is a lysosomal P-type ATPase linked to metal toxicity and autophagic and mitochondria defects in cell culture and yeast models of the disease. We generated Atp13a2 null mice to explore in vivo the normal function of this protein and to test the hypothesis that loss of Atp13a2 in mice will cause a neurodegenerative phenotype that models KRD and elements of lysosomal dysfunction relevant to PD-related neurodegeneration. Atp13a2 null mice are born at normal Mendelian frequencies and appear indistinguishable from littermate controls. These mice develop a mild, age-related hypokinetic phenotype as assessed by open field testing, but display no significant deficits when performing on the rotarod, DigiGait treadmill or balance beam. These data argue against a pronounced neurodegenerative phenotype, and preliminary neuropathological studies do not show evidence of overt neurodegeneration, accumulation of alpha-synuclein or abnormal proteinaceous inclusions. Ongoing studies of these

mice include additional neuropathological assessments, tests of epistasis with other PD-associated genes and in vitro studies to assess autolysosomal pathway function. While Atp13a2 null mice do not recapitalute many of the motor and pathological features of PD, they represent a valuable resource for understanding alterations in lysosomal biology associated with neurodegenerative disease.

Abstract: Loss of function mutations in ATP13A2, a lysosomal membrane protein of the P-type family of ion transport ATPases, underlies Kufor-Rakeb syndrome, a recently classified form of early-onset Parkinsonism with dementia (PARK9). To gain a better understanding of ATP13A2 function, we analyzed the behavioral and neuropathologic effects of the loss of this gene in mice. Knockout of the Atp13a2 gene in mice was accomplished by exchanging a region of the Atp13a2 gene encompassing exons 12-15 and the 5' half of exon 16 with a neomycin resistance gene cassette. The replaced exons include sequences encoding the phosphorylation site of the protein, which is required for enzyme activity. We then tested wildtype and Atp13a2 knockout mice on a battery of sensorimotor tests sensitive to varying degrees of neurological dysfunction including challenging beam traversal, spontaneous activity, gait, and nest building. Separate cohorts of mice were tested at 5-6, 12, and 24-27 months of age. At 5-12 months of age, there were no differences in sensorimotor function between wildtype and Atp13a2 knockout mice. However, at 24-27 months of age, the Atp13a2 knockout mice showed significant impairments compared to wildtype mice in motor performance and coordination on the beam, shortened stride length, and impairments in fine motor skills and orofacial movements involved in nestbuilding. We observed accelerated deposition of lipofuscin in the hippocampus, cortex, and cerebellum of Atp13a2 knockout mice in comparison to wildtype mice at 12-15 months of age. These results are consistent with lysosomal dysfunction that has been associated with Kufor-Rakeb syndrome. These findings indicate that loss of Atp13a2 function leads to age-dependent impairments in sensorimotor function as well as lysosomal pathology in the brain in mice. These mice will be a useful model to study the impact of the lysosomal degradation pathway in the development of features associated with Parkinson’s disease.

Abstract: Mutations in the gene encoding leucine-rich repeat kinase 2 (LRRK2) are the most common cause of familial Parkinson's disease (PD). The physiological role of LRRK2 requires further characterization although several mouse models highlight impairments in striatal dopaminergic innervation and aberrant tau phosphorylation. The LRRK2 function contributes to several neuronal phenotypes such as neuritic membrane arborization, microtubule/vesicle trafficking and autophagy. Behavioral correlates of LRRK2 genetic manipulations have yet to be rigorously tested using the same methodology across lines. In particular, behavioral paradigms reminiscent of non-motor symptoms (reflecting early pre-motor PD) have not been extensively investigated.

We report on motor, cognitive and olfactory testing for non-transgenic (NT), murine LRRK2 knockout (KO) and BAC LRRK2 wild-type overexpressing mice at 6-months of age, on C57Bl/6 background. We previously reported BAC LRRK2 G2019S L-DOPA-responsive motor deficits at 6 months, and now can directly compare results across lines.

Automated open field testing was performed to measure spontaneous horizontal and vertical locomotor activity, distance travelled, rearings and immobility time. We have also assayed physiologically-stimulated motor activity with "drag" and "accelerating rotarod" tests to assess coordination of the anterior limbs and overall motor performance, respectively.

Although PD is clinically characterized by motor deficits, depression and olfactory dysfunction are noted as early features that precede a motor phenotype, whereas mild cognitive impairment and dementia typically occur later in the course.

Herein we report initial findings in non-motor function among and across LRRK2 lines at 3 months of age. Olfactory discrimination was assayed by the habituation/de-habituation test (investigating novel odors preference) and the buried pellet test (assessing performance in finding hidden scented objects). The tail suspension test was also employed to study propensity to depressive-like states among and across LRRK2 mouse lines. Finally, we combined the use of novel object placement (spatial memory) and novel object recognition (learning abilities) to study baseline cognitive function in these mice. Comparative motor and non-motor testing will also be performed at 6 months and later time points.

Lastly, as the activity of the nigrostriatal dopamine (DA) system may correlate with both motor and non-motor phenotypes, we report on measurements of stimulated release of DA in the striatum using fast-scan cyclic voltammetry (FSCV) in acute brain slices from LRRK2 mouse lines at 3 and 6 months.

Title: Retromer (VPS35) dysfunction in Parkinson’s disease.

Authors: *A. J. MILNERWOOD[1,2], L. TAPIA[2], M. VOLTA[2], D. A. BECCANO-KELLY[2], C. VILARINO-GUELL[2], M. J. FARRER[2]

Abstract: Parkinson’s disease (PD) is a debilitating neurodegenerative disease that affects 1-2% of the population by 65 years, increasing to 4-5% by 85. Although previously thought to lack any hereditary basis, the genetic etiology of parkinsonism is becoming increasingly apparent with mutations in one protein (LRRK2) accounting for up to 40% of PD in certain ethnic populations. We recently uncovered a novel mutation causal to autosomal-dominant, late-onset parkinsonism within the vacuolar protein sorting 35 (VPS35). VPS35 is a central component of the eukaryotic retromer cargo-recognition complex, a system critical for membrane-protein recycling and endosome-trans-Golgi trafficking. A greater understanding of VPS35 biology and the pathophysiology of mutant VPS35 are essential to the development of therapeutic interventions aimed at preventing the onset and/or retarding progression of PD. Although relatively well characterized in non-neuronal cells, the physiology and regulation of the retromer system in the brain and especially in neurons is largely unstudied.
VPS35 has been shown to regulate the trafficking of several proteins involved in other neurodegenerative diseases including progranulin (PGRN, linked to fronto-temporal dementia) and the amyloid precursor protein (APP, linked to Alzheimer’s disease). VPS35 has also been implicated in actin cytoskeletal organization, synapse formation, Wnt signaling, mitochondrial peroxisome trafficking and nuclear export. To determine potential pathophysiological alterations in neuronal protein trafficking induced by mutant VPS35, we have explored the retromer binding efficiency of previously described VPS35-specific cargos in both wild-type (WT) and mutant VPS35 expressing cell lines. Furthermore, we report on the binding relationships, sub-cellular localization and the neurophysiological impact of WT and mutant VPS35 expression in primary neuronal cultures. Additionally, using a combination of yeast-2-hybrid and co-immunoprecipatation studies we have identified novel binding partners whose intracellular transport may be altered by mutant VPS35. An update will be provided on our results. Our goal

is to determine neuronal processes perturbed by mutant VPS35, and which of these disturbances are most relevant to the pathophysiology of PD. A greater understanding of these processes, in the broader context of the molecular network implicated in PD, will enable development of novel therapeutics with symptomatic and neuroprotective benefits.

Title: *In vivo* imaging of dopaminergic neuron turnover in the olfactory bulb of mouse models of Parkinson's disease

Authors: *J. NEUNER, J. HERMS
Zentrum Für Neuropathologie Und Prionforschung, München, Germany

Abstract: Dopaminergic Neurons in the adult olfactory bulb (OB) are continuously added to the pre-existing neuronal network throughout life. They are one subtype of adult-born neurons, which arrive to the OB and strive for integration as only half of them will survive. As Parkinson’s disease (PD) patients suffer from olfactory deficits from early stages of the disease on and as nerve cell loss in the PD brain mainly concerns dopaminergic neurons, we expected that this neuron population is also affected in the highly plastic OB. To follow this idea, we created a new Cre/lox mouse model of PD which both overexpresses human A30P α-Synuclein and specifically expresses the tdTomato fluorophor in its dopaminergic neurons. We showed that human A30P α-Synuclein was preferentially expressed in dopaminergic neurons of the OB. Moreover, we found that α-Synuclein overexpression notably affected the survival of specifically newborn dopaminergic neurons in our Parkinson mice. By long-term in vivo two-photon time-lapse imaging, we now followed the turnover of the tdTomato-labeled neurons through an open-skull cranial window over the OB. Thus, we traced over time the arrival of newborn dopaminergic neurons and also determined their fate to survive within the diseased OB network. Our in vivo results do not only explain olfactory malfunction in PD but also contribute to better understand the integration and the survival of the most susceptible neuron population in PD being crucial for the development of a targeted therapy.

Title: Sodium butyrate (an HDAC inhibitor) ameliorates rotenone-induced motor defects in a *Drosophila* model of Parkinson’s disease

Authors: *S. AHMAD, R. ST LAURENT
Colby Col., Waterville, ME

Abstract: Parkinsons disease (PD) is a neurodegenerative disorder primarily affecting dopaminergic neurons in the nigrastriatal pathway characterized by debilitating motor impairment. Both familial and sporadic cases of PD exhibit resting tremor, rigidity, slowness of movement, and postural instability. Histone deacetylase (HDAC) activity is misregulated in PD and other neurodegenerative diseases. Thus, HDAC inhibitors have been recently proposed as a treatment for neurodegenerative diseases. In a Drosophila model of PD, chronic exposure to the pesticide rotenone through food selectively deteriorates dopaminergic neurons and causes climbing deficits. This study investigated the effects of sodium butyrate (an HDAC inhibitor) treatment through food supplementation on motor deficits by measuring the climbing ability in a rotenone-induced PD model. We show that co supplementation of 10 mM sodium butyrate improved the climbing ability of flies exposed to 250 uM rotenone after one week. Additionally flies with the genetic knockdown of HDAC activity through Sin3A mutation, (a component of the HDAC machinery), mimicked the sodium butyrate-mediated rescue of rotenone-induced climbing deficits. Furthermore, Sin3A mutant flies raised on sodium butyrate supplemented food had an additive effect with sodium butyrate treatment for rescuing motor deficits. Therefore, sodium butyrate is presented as a treatment for rescuing rotenone-induced motor impairment in Drosophila.

Title: Automated gait analysis of the MitoPark mouse, a genetic model of Parkinson's Disease

Authors: *S. GELLHAAR, M. ABRAMS, D. GALTER
Karolinska Institutet, Dept. of Neurosci., Stockholm, Sweden

Abstract: In Parkinson´s Disease (PD), locomotor patterns, including gait disturbances and postural instability, are impaired. Some of these motor symptoms which develop also in rodent models of the disease can be monitored with several automated motor behavior and gait analysis systems. We used MitoPark mice, a genetic model of PD, to study changes in locomotor performance and gait parameters in response to treatment with different doses of L-DOPA. The CatWalk system, which has previously been used in toxin-induced models for neurological disorders, was used to complement the analysis of horizontal and vertical motor activity measured in locomotor boxes. To analyze postural instability and L-DOPA induced dyskinetic behavior in the mouse model, we assessed the behavior in the cylinder test.
MitoPark mice aged 25 weeks were treated daily with saline, 2, 8, or 16 mg/kg L-DOPA for three weeks and analyzed at two time points. The gait of saline treated MitoPark mice was impaired on day 16 showing a decreased stride length and swing speed and an increased step cycle. Treatment with 8 mg/kg L-DOPA reversed these impairments to control level. The drug induced locomotor activity tested the following day was increased, though did not reach control level.
Currently, we are analyzing the changes of gait parameters in MitoPark mice treated with the other doses of L-DOPA in an attempt to correlate them to data from the cylinder test.
Preliminary results suggest that the CatWalk system broadens the number of detectable gait changes that occur during the development of PD symptoms in MitoPark mice and is useful in monitoring the treatment success with L-DOPA, as well as with other potential drug treatments.

Title: Transgenic expression of PGC-1α protect against MPTP-induced neuronal degeneration in the mouse model of Parkinson's disease

Authors: *J. A. AGUIRRE, SR[1], V. DI LIBERTO[2], G. MUDO[2], R. CUETO[1], B. GUERRERO-STRACHAN[1], D. LINDHOLM[3], N. BELLUARDO[2]
[1]Sch. of Med., Malaga, Spain; [2]Dept. of Exptl. Biomedicine and Clin. Neurosci., Univ. of Palermo, Palermo, Italy; [3]Univ. of Helsinki, Malaga, Finland

Abstract: Mitochondrial dysfunction and oxidative stress occur in Parkinson's disease (PD). Peroxisome proliferator-activated receptor-gamma coactivator-1α (PGC-1α) is a transcriptional coactivator that is a master regulator of oxidative stress and mitochondrial metabolism. PGC-1α transgenic mice were generated using standard techniques at Uppsala University, Sweden. The levels of PGC-1α in brain tissue including substantia nigra (SN) and striatum (STR) were studied by immunoblotting using polyclonal anti-PGC-1α antibody. Mice received three i.p. injections of MPTP (14 mg/kg) within a time period of 3 h followed by a fourth injection using 7 mg/kg MPTP. Mice from the experimental groups: wild-type (WT), WT+MPTP, PGC-1α transgenic (PGC1-tg) and PGC1-tg+MPTP, were killed 7 days after the MPTP treatment using deep anesthesia and brains were collected, frozen and stored at -70°C until using. Serial 40-µm-thick coronal sections of the SN (bregma A 2.54 to A 4.04 mm) followed the stereological protocol and were processed for tyroxine-hidroxilase (TH) immunoreactivity (TH-IR) and NeuN-positive cells. Total number of TH-IR in the SN compacta (SNc) was estimated by means of unbiased stereology (CAST-Grid software package, Olympus). Coronal sections (20µm) from the STR were processed for TH-IR or anti-DA reuptake transporter (DAT) antibodies. Positive fibers and terminals were measured by densitometry. Inmunoblots for TH was used to compare the effects of MPTP on WT mice or in two different PGC-1α transgenic mouse lines: PGC11 and PGC12. Measurements of mitochondrial antioxidants SOD2 and Trx2 in the SN of PGC1-tg were also measured. MPTP caused a 60-70% depletion of DA cells bodies in the SNc in the WT wile

PGC1-tg mice overexpressing PGC-1α in dopaminergic neurons are resistant against cell degeneration induced by the neurotoxin MPTP. The increase in neuronal viability was accompanied by elevated levels of mitochondrial antioxidants SOD2 and Trx2 in the SN of transgenic mice. We show here that transgenic mice PGC-1α overexpression also protected against MPTP-induced striatal loss of dopamine. To modulate PGC-1α, we employed the small molecular compound, resveratrol (RSV) that protected dopaminergic neurons against the MPTP-induced cell degeneration almost to the same extent as after PGC-1α overexpression. The results reveal an important function of PGC-1α in dopaminergic neurons to combat oxidative stress and increase neuronal viability. RSV and other compounds acting via SIRT1/PGC-1α may prove useful as neuroprotective agents in PD and possibly in other neurological disorders.

Abstract: Parkinson’s disease (PD) is a chronic progressive neurodegenerative disorder. Genetic factors contribute to the pathogenesis of PD. PGC-1α (peroxisome proliferator activated receptor γ co-activator protein-1 α) regulates metabolic processes and brain energy homeostasis. The role of PGC-1α in the function and survival of substantia nigra pars compacta (SNpc) dopamine (DA) neurons is not clear. Here we report that there is no significant alteration of DA neurons in the SNpc of germline PGC-1α knockout mice at approximately 4 months of age. At a similar age there is only a slight loss of DA neurons in SNpc of conditional PGC-1α knockout mice using DAT-Cre. In contrast, we observe a dramatic loss of the DA neurons and down-regulation of PGC-1α target genes in mature DA neurons of the SNpc in which PGC-1α was deleted in adult animals by means of transduction of a Cre-encoding adeno-associated virus. Transgenic mice

overexpressing the PGC-1α driven by CamKII promoter show hyperactivity and a slight loss of DA neurons in the SN at approximately 4 months of age. Our findings suggest that PGC-1α is required for the survival of DA neurons in the adult SN. Moreover, appropriate levels of PGC-1α are critical for proper DA neuronal survival and function.

Title: Glutathione deficiency in gclm knockout mice results in complex i inhibition and dopamine depletion following paraquat administration.

Authors: *L. LIANG[1], T. J. KAVANAGH[2], M. PATEL[1]
[1]Pharm. Sci., Univ. of Colorado Denver, Aurora, CO; [2]Dept. Envrn. and Occup. Hlth., Univ. of Washington, Seattle, WA

Abstract: Depletion of glutathione has been shown to occur in autopsied brains of patients with Parkinson’s disease (PD) as well as in animal models of PD. In fact, GSH depletion has been suggested to be one of the earliest detectable biomarker in the PD brains, prior to selective decreases in mitochondrial complex I activity or loss of striatal dopamine. The goal of this study was to determine if GSH deficiency resulted in complex I inhibition and/or dopamine depletion and whether these indices were further potentiated by administration of paraquat, a redox-cycling herbicide. Depletion of the rate-limiting GSH synthesis enzyme, glutamate-cysteine ligase modifier subunit (Gclm) leads to significantly lower GSH concentrations in all of the tissues including brain. Gclm-null ($Gclm^{-/-}$) mice provide a model of prolonged GSH depletion to explore the relationship between GSH, complex I inhibition and dopamine loss. Despite ~60% depletion of brain GSH in $Gclm^{-/-}$ mice of ages 3-5 or 15-16 months, striatal complex I activity, dopamine levels, 3-nitrotyroine/tyrosine ratios, aconitase activity and CoASH remained unchanged. Administration of paraquat (10 mg/kg, twice/week, 3 weeks) in 3-5 month old $Glcm^{+/+}$ mice resulted in a small but statistically significant depletion of GSH and CoASH levels and increase in 3NT/tyr ratios but no changes in aconitase activity, complex I activity or dopamine levels. Administration of paraquat (10 mg/kg, twice/week, 3 weeks) in 3-5 month old

Glcm$^{-/-}$ mice resulted in further potentiation of GSH and CoASH depletion, increase in 3NT/tyr and decreased aconitase activity, complex I activity and dopamine levels. Furthermore, paraquat-induced inhibition of complex I and aconitase activities in Glcm$^{-/-}$ mice was observed in the striatum but not cortex. The results suggest that chronic deficiency of GSH in Glcm$^{-/-}$ mice was not sufficient to result in complex I inhibition or dopamine depletion perhaps due to homeostatic mechanisms but required an additional oxidative stress insult i.e. paraquat exposure.

Title: Characterization of the role of Regulator of G-Protein Signaling 10 in aging murine substantia nigra pars compacta

Authors: *C. P. RAMSEY, M. G. TANSEY
Physiol., Emory Univ., Atlanta, GA

Abstract: Parkinson's disease (PD) is the most common progressive neurodegenerative movement disorder. The motor symptoms of PD are caused by nigrostriatal dopamine deficiency due to the loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc) in the midbrain. To date, a single cause for PD has yet to be identified; however, it is known that the risk for PD onset increases with age. Thus, it is of interest to understand the underlying mechanisms of PD pathogenesis, especially those related to the normal aging process. Previous studies from our group have shown that the GTPase activating protein (GAP), Regulator of G-protein signaling (RGS)-10, plays an in vivo role at protecting nigral dopaminergic neurons from extrinsic inflammatory stimuli. However, it is not known whether RGS10 is required to promote nigral neuronal health without the addition of external insult. Neither is it known whether the in vivo role for RGS10 changes during aging. To address these questions, in the study herein, young (3-5 month old) and aged (18-20 month old) RGS10 null and wild-type (WT) mice will be compared. Ventral midbrain (VMB) and striatum tissues from the mice will be analyzed by QPCR to detect changes in PD-related gene expression that are caused by aging and RGS10

function. The identified altered genes will be assessed by quantitative immunoblot using VMB and striatum tissue extracts. Additionally, co-immunoprecipitation studies will be conducted to determine whether RGS10 forms direct protein interactions with the gene products that are found to be altered in the quantitative immunoblot studies. Lastly, unbiased stereology experiments will be conducted in aged mouse SNpc to determine whether RGS10 is required to promote nigral neuronal health during aging.

Title: Expression and function of nurr1 in nurr1 null heterozygous genotype and aging

Authors: *E. KUMMARI, J. B. EELLS
Basic sciences, Mississippi State Univ., Mississippi State, MS

Abstract: Dopamine neurons from different dopaminergic populations like the nigrostriatal, mesoaccumbens and mesocortical regions are anatomically and functionally different. Determining the expression patterns of Dopamine genes and proteins involved in Dopamine neurotransmission in various dopaminergic populations and the regions they innervate in young and aged, heterozygous and wild type mice is the goal of this study. Nurr1 (NR4A2) is a transcription factor that is needed for the development and sustenance of dopamine neurons and has been implicated to play a major role in regulating the expression of dopamine neurotransmission genes like Tyrosine hydroxlase (TH), Dopamine transporter (DAT), Vesicular monoamine transporter (VMAT) and GTP cyclohydrolase (GTPCH). Previous research found that Nurr1 is reduced during aging and that dopamine neuron function in Nurr1 null heterozygous mice is more susceptible to aging. The current experiment investigates how the Nurr1-null heterozygous genotype affects protein expression in young and aged mice. Brain sections of both Nurr1 wild type and Nurr1 null heterozygous mice were immunohistochemically treated using Nurr1 antibody and the quantity of Nurr1 determined by studying the cumulative signal strength of the chromogen staining. The wild type showed higher expression of Nurr1 in

the Ventral Tegmental Area (VTA) regions compared to the heterozygous. We will further investigate the expression of Nurr1 in Substantia Nigra Pars compacta (SNpc) as well as the expression levels of GTP cyclohydrolase, Dopamine transporter and tyrosine hydroxylase in dopamine target regions in young and aged Nurr1 wild type and Nurr1 null heterozygous mice. Understanding the interaction of aging and expression of these proteins involved in dopamine neurotransmission could give us important insight into understanding Parkinson's disease.

Title: Reduced expression of the vesicular monoamine transporter (VMAT2) disrupts catecholamine homeostasis and causes progressive neurodegeneration in mice

Authors: *S. ALTER[1], T. N. TAYLOR[2], P. SULLIVAN[3], D. S. GOLDSTEIN[3], G. W. MILLER[1]
[1]Envrn. Hlth., Emory Univ., Atlanta, GA; [2]Univ. of Minnesota, Minneapolis, MN; [3]NINDS, Natl. Inst. of Hlth., Bethesda, MD

Abstract: PD features the progressive loss of catecholamine neurons in the substantia nigra pars compacta (SNc), the locus coeruleus (LC), and the autonomic nervous system. We have previously reported that mice deficient in VMAT2 expression (Slc18a2) undergo progressive nigrostriatal degeneration, monoamine depletion (DA, NE, 5-HT), and exhibit both motor and nonmotor symptoms of Parkinson's disease (Caudle, J. Neuroscience, 2007; Taylor, J. Neuroscience, 2009).
Here, we report parallel disruptions in the norepinephrine and dopamine systems of VMAT2-deficient mice. Unbiased stereological analysis reveals that VMAT2-deficient mice undergo progressive LC degeneration beginning at 12 months of age, preceding SNc degeneration at 18 months. LC degeneration is accompanied by reductions in norepinephrine transporter (NET) immunoreactivity throughout the brain including the hippocampus and bed nucleus of the stria terminalis (BNST). Quantitative analysis of NET abundance in the brain and sympathetically

innervated peripheral tissue is being performed with 3H-nisoxetine binding.
In addition to their neurodegenerative phenotype, VMAT2-deficient mice also exhibit alterations in catecholamine homeostasis. HPLC analysis revealed increased ratios of DHPG:NE (foldchange in cortex, 1.91; striatum, 1.83; hippocampus, 1.71) and drastic increases in DOPAC:DA (foldchange in cortex, 15.2 ; striatum, 15.1; hippocampus, 18.7), indicative of increased cytosolic catecholamine metabolism. These aberrations are not limited to the central nervous system: VMAT2 deficient hearts show a 97% reduction in norepinephrine and a 10-fold increase in cardiac DHPG:NE.
These data describe an animal model of aberrant catecholamine metabolism and progressive catecholaminergic degeneration. The severity and staging of cell loss and changes in catecholamine metabolism are also observed in PD patients. The observed changes in the cardiac NE system are also noteworthy, as there is a strong comorbidity of cardiac denervation in human PD. These findings demonstrate that reduced catecholamine storage in an in vivo model is sufficient to produce progressive catecholaminergic neurodegeneration in brain and peripheral regions affected in PD.

Title: Evaluation of non-motor behaviors in DJ-1-deficient mice.

Authors: V. P. CHOU, A. S. MOALEM, *J. ORDUNA, J. MONTENEGRO, T. V. KHROYAN, N. KO, A. B. MANNING-BOG
SRI Intl., MENLO PARK, CA

Abstract: To investigate the relationship between DJ-1 and non-motor features related to Parkinson’s disease (PD), we utilized a mouse model of DJ-1 deficiency (i.e. Exon 7 insertion).

At ages 6 and 12 months (n = 10-12 per genotype per age), behaviors were assessed using a battery of non-motor testing paradigms including a food retrieval task, the elevated plus maze and the novel object recognition assay. In the buried pellet task, time to locate and retrieve normal chow was compared between null DJ-1 mice and their wild-type (WT) littermates using a 10-day testing regimen. In the initial five days of testing, no apparent difference in time to find food pellet was detected between null DJ-1 and WT mice. Subsequently, WT mice displayed a steep learning curve with this cohort requiring 97% less time to retrieve food from day 5 to 7 ($p < 0.01$); this effect was sustained in the WT mice for the remainder of the paradigm. In comparison, the null DJ-1 cohort showed only modest improvements in retrieval time, and at days 7-10 required significantly more time to complete the task (approximately 3-fold compared to WT; $p < 0.01$). Such changes were noted in the aged cohort only. These data indicate that aged null DJ-1 mice may have impaired olfaction and/or cognition compared to WT. In the elevated plus maze paradigm, anxiety-like behavior and memory deficits were evaluated. While no significant differences in time spent and entries into closed arms due to genotype were detected in the younger cohort, a significant increase in time spent by WT vs. null DJ-1 in the open arm was revealed (approximately 1.9-fold; $p < 0.05$). In the aged groups, null mice had significantly fewer entries into the open space vs. WT (40% reduction; $p < 0.05$). These data indicate age-related alterations in anxiety and cognition in DJ-1 null mice.. It is also important to note that total distance travelled during the assay by DJ-1 null mice was also decreased as compared to WT, consistent with previous findings from our lab and others that motor activity is reduced. Lastly, using the novel object recognition (NOR) task, memory was assessed. In the younger cohort, both null DJ-1 and WT animals spent significantly more time with the novel vs. familiar object. However, in the aged group, while WT mice had greater exploration time with the novel object (2.7-fold increase; $p < 0.005$), the null DJ-1 cohort equivalently explored the familiar and novel object. These data suggest impaired memory in the transgenics. Taken together, these non-motor behavior assays indicate that DJ-1 deficiency in mice may promote impairment of non-motor behaviors reminiscent of those noted in PD.

Title: Analysis of dopaminergic and serotonergic systems in Parkin and DJ-1 knockout mice as models of loss-of-function mutations linked to Parkinson's disease.

Authors: *M. R. HENNIS, M. A. MARVIN, M. S. GOLDBERG
UT Southwestern, Dallas, TX

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disease, after Alzheimer's disease and afflicts over a million people in the United States alone. PD is an age-dependent disease that causes progressive death of dopamine-producing neurons within the brain. The loss of dopamine neurons results in locomotor symptoms such as slowness of movement, tremor, rigidity and postural instability. Recent studies indicate that other neurotransmitters, such as serotonin, may also be involved. There are currently no therapies proven to halt or slow down the progressive neuronal cell loss in PD. To achieve this goal, it is important to understand the cause of PD at the molecular and cellular level. Although most cases of PD are sporadic, many families show a Mendelian pattern of inherited parkinsonism and causative mutations have been identified in genes such as Parkin, DJ-1, PINK1, alpha-synuclein and Leucine Rich Repeat Kinase 2 (LRRK2). Additionally, the activity of glutathione peroxidase 1 (Gpx1), a major antioxidant protein, is reduced in PD brains. We crossed mice deficient for both Parkin and DJ-1 with mice deficient for Gpx1 to test the hypothesis that loss-of-function mutations in Parkin and DJ-1 cause PD by increasing susceptibility to chronic oxidative stress. Surprisingly, mice lacking Parkin, DJ-1 and Gpx1 have increased striatal dopamine levels in the absence of nigral cell loss compared to wild-type, single, and double mutant mice. Mice lacking Parkin and DJ-1 exhibit improved rotarod performance and have increased serotonin in the striatum, hippocampus and prefrontal cortex. We performed stereological analysis of immunostained serotonergic processes in the hippocampus to determine whether the increase in serotonin we observed by HPLC analysis is due to an increase in serotonergic projections. The results of our behavioral, neurochemical and immunohistochemical analyses indicate that PD-linked mutations in Parkin and DJ-1 cause dysfunction in neurotransmitter systems beyond the nigrostriatal dopaminergic circuit.

Abstract: Loss of function mutations of the DJ-1 gene (Park7) are associated with a familial form of autosomal-recessive early-onset Parkinson's disease (PD). DJ-1 is a 189 amino-acid protein whose function appears to be multifunctional as it has the properties of an antioxidant, can regulate transcription and RNA binding, serve as a chaperone, and may play a role in apoptosis. In partnership with the Michael J. Fox Foundation for Parkinson's Research, Sigma Life Science, using zinc-finger nuclease technology, has developed the DJ-1 homozygous knockout (KO) rat. This novel rat genetic model, only recently available, has yet to be phenotypically characterized and presents an excellent opportunity to investigate the role of DJ-1-related mitochondrial dysfunction and oxidative stress in experimental parkinsonism in an animal model that is more amenable to behavioral, neuroanatomical, and functional study than the mouse. The present study represents the initial behavioral phenotyping of DJ-1 KO rats with the goal of shedding light on possible sensorimotor and non-motor deficits resulting from the loss of function mutation of the PD-linked DJ-1 gene in this model. Male wildtype and DJ-1 KO rats are being tested on a battery of behavioral tests to assess both sensorimotor and non-motor functions. Sensorimotor assessment includes tests of gait, response to somatosensory stimuli, movement initiation, and bracing. Non-motor assessment includes tests of anhedonia, emotional reactivity, and attention. We found alterations in several sensorimotor parameters in DJ-1 knockout compared to wildtype rats. At two months of age the stride variability is significantly different in DJ-1 compared to wildtype rats and at four months of age DJ-1 knockout rats show significantly different rearing and hindlimb stepping in the cylinder compared to wildtype controls. Body weights also differed at four months of age with DJ-1 knockout rats weighing significantly more that wildtype controls. Analysis of non-motor behavior is ongoing. The novel DJ-1 rat model may prove useful in understanding the underlying molecular mechanisms that eventually lead to the development of PD, which could inform novel therapeutic targets for treatment.

Title: Dna repair deficiency accentuates the parkinson related phenotype in the dj-1 knockout mice

Authors: M. Y. SANCHEZ-CONTRERAS[1], J. LYDA[2], *F. CARDOZO-PELAEZ[3]
[1]CEHS- BMED, [2]CEHS-BMED, Univ. of Montana, Missoula, MT; [3]Biomed & Pharmaceut Sci., Univ. Montana, MISSOULA, MT

Abstract: Parkinson's disease (PD) is considered to be a multifactorial disease involving genetic, environmental or the interaction of both factors in its etiology. Loss-of-function mutations in DJ-1 gene have been associated with autosomal recessive early-onset PD. Although a precise role for DJ1 defects in PD remains unknown, DJ1 may function as a redox-sensitive chaperone and protecting neurons against oxidative stress and cell death. In previous studies, we have shown that mice lacking the DNA repair enzyme 8-oxoguanine glycosylase 1 (OGG1 KO), present an age-dependent mild parkinsonian phenotype, which supports that increased oxidative damage to the DNA may play a role in the nigrostriatal system dysfunction in PD. Furthermore, we showed that DJ-1 KO mice can be protected from MPTP-induced dopaminergic loss by inducing neuronal-specific expression and activity of Ogg1 in the substantia nigra suggesting that DNA damage plays a major role in protecting DA neurons during aging and in PD-related neurotoxicological. We generated DJ1/OGG1 double KO (DKO) mice and reported that they exhibit an early-onset and age-dependent bradikynetic phenotype consisting of reduced speed, increased immobility and decreased rearing activity. This diminished motor behavior phenotype is responsive to dopamine agonists. We treated DJ-1/OGG1 DKO mice with the dopaminergic precursor L-DOPA and with the dopaminergic receptor agonist apomorphine at different age

points. When treated with L-DOPA, 12-month-old DJ-1/OGG1 DKO mice increased 137% in speed. This L-DOPA-induced increment in the speed constitutes a significant improvement of DJ-1/OGG1 DKO mice reaching to a normal behavior level (1.02cm/s±0.2 basal to 1.12cm/s±0.2 L-DOPA). Additionally, we assessed the susceptibility of DJ-1/OGG1 DKO to the dopaminergic toxin MPTP at 3 months of age. We found that DJ-1/OGG1 DKO was more susceptible than WT mice (71.8% vs. 32% reduction in striatal DA, from saline treated). Even more, DJ-1/OGG1 DKO mice lost more striatal dopamine than the single DJ-1 KO (48.8%) and OGG1 KO (27.3%). Current studies are assessing whether neuronal-specific Ogg1 expression protects DJ-1/OGG1 DKO against MPTP. Our findings add further evidence to the role of DNA damage in the age-related dysfunction of the dopaminergic system observed in PD. Supported by NIA grant RO1AG031184, NIH P20 RR015583 and NIH P20RRP20RR017670.

Title: Aged H-ferritin-deficient mice as a model for Parkinson’s Disease

Authors: *A. M. ILL SNYDER[1], E. B. NEELY[1], E. L. UNGER[2], J. R. CONNOR[1]
[1]Neurosurg., Penn State Univ. Coll Med., HERSHEY, PA; [2]Nutr., Pennsylvania State Univ., University Park, PA

Abstract: Age is one of the most significant risk factors in the onset of neurodegenerative disease and oxidative stress in the brain increases with age. A key component to oxidative stress is iron accumulation without coinciding increases in proteins that manage iron, such as ferritin. Iron deposition is particularly apparent in the substantia nigra and is thought to be a major factor in the progression of the dopaminergic cell death seen in Parkinson’s disease. Therefore, the component of age is an important factor in modeling PD in animals and current animal models of PD do not show age-dependent vulnerability.
In a mouse model that is deficient for the iron management protein H-ferritin, we found that neurotoxin challenge with paraquat and maneb does not affect cell viability in 4-month old mice; however, 12-month old mice that are deficient in H-ferritin exhibit a 35% loss of cells as compared to age-matched saline-treated controls and a 28% loss of cells compared with H-

ferritin-deficient animals treated with saline.
Our data demonstrate that the number of DAergic cells and the amount of TH protein in the unperturbed nigra is unaffected by H-ferritin deficiency at 4 or 12 months of age. Further examination of the nigrostriatal pathway and revealed no change in iron content or DAT. Taken together, these data suggest that the DAergic neurons in the aged H-ferritin-deficient mouse are vulnerable to the effects of paraquat and maneb in ways that are beyond the “classical” iron-mediated pathways.
This led to the hypothesis that changes in trophic factor profiles or alterations in mitochondrial proteins are important factors in identifying the cause of the age-dependent host susceptibility of neurons. MANF (mesencephalic astrocyte-derived neurotrophic factor) levels were increased in H-ferritin-deficient mice at both 4 and 12 months of age. Mitochondrial COX IV protein levels were unchanged due to age or genotype. Mitochondrial ferritin, which is structurally and functionally similar to H-ferritin, was not able to be detected histologically or by immunoblotting.
The collective data from these experiments suggest that the H-ferritin deficient mice offer a model of age-dependent host susceptibility for the study of PD. The increased host susceptibility is not simply due to iron accumulation with age or loss of DAT expression. Studies are in progress to continue to interrogate our hypothesis that there are compensatory mechanisms in place in the 4-month-old H-ferritin-deficient mice that enable neuronal survival following neurotoxins, but by 12 months of age, this compensatory profile is no longer in place or is no longer adequate to protect the neurons.

Title: Enhanced sensitivity to chronic MPTP exposure in HuA53TαS overexpressing mice

Authors: *J. BARNES[1], Y. LIU[2], N. XIONG[1], T. N. TAYLOR[1], B. THOMAS[3], M. K. LEE[1]

Abstract: Parkinson's Disease (PD) is the second most-common neurodegenerative disease worldwide after Alzheimer's Disease and affects ~1% of the population over 65 years of age. While there are known genetic causes of PD, the vast majority of cases are idiopathic. Of the identified heritable PD-causing factors, three mutations in the gene encoding the 140-amino acid protein α-synuclein (αS) have been shown to cause an early-onset familial form of the disease. In addition, environmental dopaminergic (DAergic) neurotoxins are implicated in PD. The relationship between αS and toxin vulnerability, however, has been uncertain because mutant αS does not increase the sensitivity of DAergic neurons to acute toxin exposure.
To study whether a more chronic stress would reveal pathological interactions between αS and DAergic neurotoxins, we tested whether mice overexpressing A53T mutant human αS (HuA53TαS, line G2-3) are hypersensitive to the neurotoxic effects of 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP). We used a chronic MPTP model in which osmotic mini-pumps loaded with MPTP were implanted sub-cutaneously in male mice for 28 days (delivering 30 mg/kg of MPTP per day). Transgenic (HuA53TαS overexpressing) and non-transgenic (nTg) mice aged 4-6 months were utilized for all experiments. All mice were asymptomatic at the time of surgery. As observed previously with this chronic MPTP-induced model of PD, the treatment paradigm resulted in a marked loss of DAergic neurons in the substantia nigra pars compacta as well as a decrease in total locomotor activity in the open-field test in all mice. Importantly, however, HuA53TαS mice were more sensitive to the effects of MPTP, showing a greater loss of DAergic neurons and locomotor activity than control animals. Our results thus show that increased expression of mutant HuA53TαS leads to increased vulnerability of DAergic neurons to chronic toxin exposure but not acute toxicity.

Abstract: Parkinson's disease (PD) is a chronic neurodegenerative disease of dopaminergic circuits, characterized by motor and non-motor symptoms. Animal models of PD have helped understanding basic neurodegenerative mechanisms of the disease, and are ideal tools to test new therapies for PD. One of the most used models is the 6-hydroxydopamine (6-OHDA) unilaterally-lesioned rat, in which motor deficits are well described. However, information regarding changes in other behavioral dimensions is scarce. Thus, this work aimed at improving the characterization of this model, hoping to reveal additional phenotypic hallmarks, useful in the future to address, beyond the motor level, the relevance of novel treatments. Furthermore, we were interested in assessing the effect of dopaminergic and antidepressant therapy in any changes encountered, particularly at the motor and mood levels.
Wistar-Han rats were unilaterally injected with 6-OHDA or saline in the MFB. Behavioral assessment addressed motor, emotional and cognitive dimensions, together with apomorphine-induced turning behavior. Post-mortem, we performed tyrosine hydroxylase immunohistochemistry to quantify nigral dopaminergic cell loss. To study the effect of dopaminergic and antidepressant therapy a second set of animals was used. Animals were treated daily with one of three compounds: levodopa (25mg/kg), paroxetine (6mg/kg) or bupropion (10mg/kg). During treatment behavioral analysis was repeated.
Apomorphine-induced turning behavior and histological analysis revealed the existence of two animal clusters in the 6-OHDA-lesioned group. Animals with severe lesions displayed significant motor impairments, decreased exploratory activity, depressive-like behavior and impairments in cognitive flexibility. Animals with incomplete lesions, relatively spared at the motor level, showed depressive-like behavior and changes in exploratory activity. Moreover, we found that both levodopa and antidepressant therapy was effective on improving lesion induced behavioral changes.
Our work shows that the unilateral model of PD presents behavioral changes beyond the motor level, which can be improved with both dopaminergic and antidepressant therapy. Thus, this can be a useful model to test the impact of PD-targeted therapies in a multidimensional fashion.

Title: The JAX Parkinson’s disease mouse model repository: Characterization of novel strains

Authors: *M. SASNER[1], M. A. OSBORNE[1], K. WARDWELL[1], C. M. LUTZ[1], R. WILPAN[1], R. LYNCH[1], D. HINERFELD[1], K. D. DAVE[2]
[1]The Jackson Lab., BAR HARBOR, ME; [2]The Michael J. Fox Fndn. for Parkinson's Res., New York, NY

Abstract: The Parkinson’s Disease Mouse Model Repository (PDMMR) at The Jackson Laboratory serves as a central resource to select and obtain PD mouse models for basic research and therapy development. In addition to distributing a large set of previously published strains, we are working in collaboration with The Michael J. Fox Foundation for Parkinson’s Research with the goals of creating improved models that more closely mimic human disease, and making mice available for both academic research and therapy development in the pharmaceutical and biotechnology sector. Extensive molecular and phenotypic characterization information is being developed to identify novel lines with highest expression levels and to compare these new mice to existing strains to enable users to choose the best model for a specific application.
The repository provides a collection of previously published strains such as alpha-synuclein (SNCA) transgenic mice that include A53T, A30P, and wild-type human alleles driven in distinct neuronal subsets by various transgenic or the endogenous promoter; novel SNCA lines have been developed and are being characterized. Some of the SNCA mutants display motor deficits, alpha-synuclein inclusions and neurodegeneration similar to that seen in PD patients. A mouse model expressing the human PARK2*Q311X allele driven in dopaminergic neurons by the Slc6a3 (DAT) promoter displays late-onset and progressive Parkinson's disease pathogenesis. Previously established BAC transgenic lines expressing mutant human alleles of LRRK2 are being compared to novel BAC transgenic lines carrying the D1994A, G2019S, and R1441G mutations. Available knockout strains carry deletions in the alpha-, beta-, and gamma-synuclein, Lrrk1, Lrrk2, Pink1 and Park2 (Parkin) and Park7 (DJ-1) genes. This collection affords users the opportunity to create novel combinations of alleles to better understand the molecular pathways involved in PD and potentially make better disease models; for example, a SNCA transgenic/Pink1 knockout strain displays an earlier phenotype than the strains with the single

alleles.
We are actively seeking additional Parkinson's disease mouse models. Submission of a strain to the repository, which can be initiated via a web form, fulfills requirements for sharing of mice in accordance with NIH's policy for sharing of research reagents. If necessary, donating investigators can place licensing restrictions on the distribution and use of their models. For more information about the PDMMR including a list of strains, phenotype descriptions, allele and genotyping information and associated references, see
http://research.jax.org/grs/parkinsons.html

Title: MJFF animal models 2: Generation, characterization, and distribution of LRRK2 animal models for Parkinson's research

Authors: *M. A. BAPTISTA[1], K. D. DAVE[1], S. DE SILVA[1], M. SASNER[2], A. GORODINSKY[3], M. J. BECK[4], C. QUANG[4], K. GAMBER[5], A. REITH[6], J. LYON[6], A. ROULOIS[6], Y. AZIZ[1], S. S. DAS[1], J. L. EBERLING[1], A. DUFOUR[1], M. F. FACHERIS[1], B. K. FISKE[1], N. SHETH[1], T. B. SHERER[1], A. URKOWITZ[1], M. FRASIER[1]
[1]Michael J. Fox Fndn., New York, NY; [2]The Jackson Lab., Bar Harbor, ME; [3]Taconic, Cranbury, NJ; [4]WIL Res. Labs., Ashland, OH; [5]SAGE, Saint Louis, MO; [6]GlaxoSmithKline Pharmaceuticals R&D, Stevenage, United Kingdom

Abstract: Determining the efficacy of LRRK2 inhibitor therapeutics has been a challenge due to the lack of availability and systematic characterization of LRRK2 animal models. The existing LRRK2 animal models have not closely recapitulated PD-related CNS pathology and symptomology, resulting in limited translation of preclinical findings. MJFF is generating, characterizing, and distributing LRRK2 animal models in an effort to make them available at cost without any restrictions on use for the entire research community. MJFF is generating 15 LRRK2 transgenic/knockout rodent lines, out of which 4 lines (LRRK2 WT mouse, LRRK1 KO mouse, LRRK2 KO mouse, LRRK2 KO rat) are currently available. To date, MJFF funding has facilitated distribution of over 1500 LRRK2 transgenic rodents to both non-profit organizations

and industry. To generate new animal models, founder lines are selected at Taconic based on genotyping, mRNA/protein expression, and copy number data, and transferred to Jackson Labs for re-derivation. Using this process, MJFF has recently generated a BAC human LRRK2 wild type mouse that has approximately 5 fold expression over endogenous LRRK2, with the R1441G, G2019S, D1994A and A2016T mutants to be generated soon in the hope that a robust phenotype will emerge. As part of the strategy to standardize and replicate published phenotypic data, MJFF has initiated the breeding and aging of both MJFF-generated and pre-existing LRRK2 models. For example, BAC human R1441G LRRK2 transgenic mice (Li et al., 2009) were aged to 4, 8, and 12 months and behavioral (rotarod, catalepsy, balance beam, and open field, etc.), neurochemical (striatal neurotransmitter concentrations), and histological (staining for alpha-synuclein, tyrosine hydroxylase, etc.) outcome measures were determined. MJFF preliminary results indicate that while there is no behavioral phenotype evident in 4 and 8 month BAC R1441G mice (Li et al., 2009), striatal dopamine and 5-HT levels are statistically lower than non-transgenic controls at 8 months of age. MJFF is also characterizing phenotypes associated with the toxic effects of knocking out LRRK2 in order to mitigate the risk of therapeutically targeting LRRK2. MJFF generated LRRK2 KO rats have no behavioral or neurochemical deficits up to 12 months of age. Since LRRK2 KO mice exhibit kidney pathology (Herzig et al., 2011; Tong et al., 2012), MJFF is currently investigating if there are similar morphological differences in kidneys of LRRK2 KO rats. All phenotypic data will be shared by creating a public database.

Engin. Labs, Saint Louis, MO

Abstract: Recessively inherited loss-of-function mutations in the Parkin, DJ-1 or PINK1 gene are linked to familial cases of early-onset Parkinson's disease (PD). Single knockout (KO) mice (lacking either Parkin, DJ-1 or PINK1) and triple-knockout (lacking all three genes) exhibit disruptions of dopamine homeostasis but no dopaminergic degeneration in the substantia nigra (SN). As part of the strategy to provide more tools for the research community, The Michael J. Fox Foundation for Parkinson's Research (MJFF) has funded the generation of novel rat models lacking either Parkin, DJ-1 or PINK1 genes. Additionally, MJFF sponsored a standardized characterization including behavioral, neurochemical and pathological measures to determine if these rats exhibit progressive PD-like phenotype. The PINK1 KO rats demonstrated motor dysfunction and gait impairment compared to wild-type rats (WT), and some of these deficits were progressive starting as early as 8-weeks of age and continuing up to 8-months of age. These deficits included increased hind-limb foot slips in the tapered beam test, decreased rearing in fatigue challenge test, loss of hind-limb grip strength, impaired mobility in the open-field, gait disturbances in the Neurocube, lack of hind-limb extensor strength, decreased air-righting reflex and reduced muscle tone. The DJ-1 KO rats expressed similar motor and gait abnormalities, however these deficits were less pronounced and appeared mostly between 6 and 8 months of age. At 8-months of age, both PINK1 KO and DJ-1 KO rats showed a significant two-three fold increase in both striatal dopamine and serotonin content compared to WT, however, there were no robust differences in DOPAC, HVA and 5-HIAA levels. Moreover, stereological estimation in both PINK1 KO and DJ-1 KO rats showed a progressive loss of TH-positive neurons of the pars compacta of SN with 50% loss observed at 8-months of age compared to WT. There were no significant differences observed in the Parkin KO rats compared to WT in behavior, striatal neurotransmitter content or numbers of SN dopaminergic neurons up to 12-months of age. Characterization of alpha-synuclein immunoreactivity in these rat models is currently ongoing. These results demonstrate that loss of either the PINK1 or the DJ-1 gene in the rat produces a progressive loss of dopaminergic neurons, and that this neurodegeneration may be correlated to progressive motor and gait deficits. Thus, these MJFF-generated PINK1 and DJ-1 KO rats will help elucidate the mechanisms by which these recessive genes produce PD pathology and aid in therapeutic development.

Title: Id2 inactivation results in biphasic ambulatory abnormalities and age-dependent histologic changes in the substantia nigra pars compacta

Authors: *M. C. HAVRDA, B. PAOLELLA, N. WARD, K. HOLROYD
Dartmouth Med. Sch., Lebanon, NH

Abstract: Characterizing dopaminergic neuronal development and function may uncover strategies for researchers to develop disease-modifying treatments for neurodegenerative diseases, such as Parkinson’s disease (PD). Id2 encodes a helix-loop-helix transcriptional repressor highly expressed in the developing central nervous system (CNS). Id2-/- mice have fewer dopaminergic neurons in the olfactory bulb associated with reduced olfactory discrimination, a pre-clinical marker of PD. Behavioral, histologic and in vitro molecular biological analyses indicated that midbrain dopaminergic neurons were also affected by Id2 loss. Id2-/- mice were hyperactive at 1 and 3 months, but by 6 months, showed reduced activity. Histologic examination of Id2-/- mice showed age-dependent loss of dopaminergic neurons in the substantia nigra pars compacta (SNpC) correlated with changes in ambulatory activity. Indicators of neurodegeneration including activated caspase-3 and glial infiltration were noted in the SNpC of older Id2-/- mice. Reduced DAT expression was observed in Id2-/- mice in vivo as well as in an in vitro dopaminergic differentiation model. These findings indicate that Id2 has a critical role in the maintenance of midbrain dopamine neurons. The Id2-/- mouse is thus a suitable animal model to study the progression of neurodegenerative disorders involving the dopamine system.

Title: Knockout rat models for Parkinson’s disease

Authors: *E. V. KOURANOVA[1], D. FISHER[2], Y. WU[1], E. WEINSTEIN[1], X. CUI[1]
[1]SAGE Labs, [2]Sigma Aldrich, Maryland Heights, MO

Abstract: The rat is a superior choice to the mouse for studying human neurological diseases due to a more sophisticated brain. Until recently, targeted rat genome manipulation was not possible due to the lack of experimental tools used to alter the rat genome. In 2009, Geurts et al. created the first Zinc finger nuclease (ZFN)-mediated knockout rats by microinjection of ZFNs into single-cell embryos (1). ZFNs are fusion proteins of a zinc finger protein and the DNA endonuclease domain of a type II restriction enzyme, *Fok*I. ZFNs are engineered to bind and cleave at specific chromosomal locus to generate double strand breaks, repair of which by the non homologous end joining pathway results in insertions/deletions that potentially disrupt the gene function.

Most Parkinson’s disease (PD) cases are sporadic in origin, and the less common familial forms are linked to a number of genes, including the following most studied five: Parkin (Park2), PINK1, DJ-1 (Park7), α-synuclein and Lrrk2. Mouse knockout models have been made against these genes and show alterations within the nigrostriatal dopamine system but lack Parkinsonism phenotypes such as loss of dopaminergic neurons in the substantia nigra and the development of protein inclusions called Lewy bodies (2). We created four knockouts against the above five genes using ZFN technology. Western blots analysis showed the total lack of respective proteins in these models. We will report expression profile changes via PCR array analysis as well as available brain imaging and behavior data. These models will potentially help elucidate the molecular mechanisms that underlie PD and facilitate drug development.

Abstract: Parkinson's disease (PD) is classically characterized by motor symptoms; however, non-motor manifestations are increasingly recognized as relevant in this condition. Given the influence of these non-motor symptoms in the well-being of PD patients it is of major interest to assess these features in studies using PD animal models. Therefore, the present study aims to compare the motor, emotional and cognitive behaviour of three rat models of PD.
The models analyzed were the 6-OHDA lesion model, paraquat (PQ) model, and a genetic model based on α-synuclein overexpression. 6-OHDA and AAV-α-synuclein vector were injected bilaterally in the substantia nigra of adult male Wistar rats. For PQ delivery, micro-osmotic pumps were implanted in the interscapular region. After surgeries the animals were allowed to recover for five weeks before starting the behavioural assessment. The motor, emotional and cognitive performances were assessed through different paradigms: spatial reference and working memory tests, forced swimming test, sucrose preference test, open field, elevated plus maze and rotarod. All the models exhibited motor deficits. In addition to motor impairments the animals of α-synuclein model presented also a reduction of exploratory activity as well as an increase in anxiety-like behavior. Animals exposed to 6-OHDA and PQ also displayed a

significant increase in anxiety-like behavior. Interestingly, only in the 6-OHDA model there was an increase in depressive-like behavior. Learning and memory tasks were not affected by treatments, suggesting that these cognitive domains are not affected in these PD models. Overall, these PD models are suitable for mimicking the motor symptoms, and some of them encompass also other relevant components of the disorder.

Title: Impact of cortical alpha-synuclein overexpression on the performance in operant tasks of cortico-striatal function

Authors: *H. S. LINDGREN[1], A. KLEIN[2], A. HEUER[1], S. B. DUNNETT[1]
[1]Cardiff Univ., Brain Repair Group, Cardiff, United Kingdom; [2]Hannover Med. Sch., Hannover, Germany

Abstract: Although Parkinson’s disease (PD) has traditionally been considered a pure motor disorder, impairments in cognition are increasingly recognized among the non-motor symptoms with significant clinical impact. More specifically, cognitive impairments typically fall within the ‘executive’ domain, affecting functions such as cognitive flexibility and rule learning. Cortical and subcortical pathological accumulation of intracellular alpha-synuclein aggregates are considered to be a key factor to this cognitive decline.
Rats were pre-trained on an operant version on the classical delayed alternation task before receiving an injection of adeno-associated viral vectors (AAV) encoding for alpha-synuclein into the medial prefrontal cortex. Another subset of animals received excitotoxic lesions of the same prefrontal region and all rats were re-tested on the delayed alternation task twelve weeks post-injection. Overexpression of alpha-synuclein in medial prefrontal cortex had no effect on

performance in this operant task with rats displaying choice accuracy in the same range as the sham-lesioned controls. In contrast, rats with an excitotoxic lesion of the medial prefrontal cortex were significantly impaired, showing a reduced choice accuracy at all delays, suggesting that the deficit is one of frontal-type executive function rather than of short-term memory. Considering the involvement of prefrontal cortex in cognitive flexibility, the rats are now being trained on an operant reversal-learning task and their performance will be assessed and compared among the different lesion-groups. After completion of the operant testing, tracer injections, histological and biochemical assessments of alpha-synuclein expression and neuronal pathology will be performed and correlated to the performance in these operant tasks.

Title: Overexpression of α-synuclein impairs learning and memory and cholinergic mini-synaptic currents in *Drosophila*.

Authors: *Z. PEI[1], X. ZHAO[2], L. CHEN[2], X. SU[1]
[1]Dept. of Neurol., The First Affiliated Hospital, Sun Yat-Sen Univ., Guangzhou, Guangdong, China; [2]Neurol., Sun Yat-sen Univ., Guangzhou, China

Abstract: Parkinson’s disease (PD) is the most common degenerative disease of the nervous system besides Alzheimer’s disease. Both genetic and environmental factors contribute to the etiology of PD. Pathologically, the symptoms of PD are mainly caused by nigrostriatal dopaminergic nerve cell loss or the decline of remnants dopaminergic neurons in dopamine biosynthesis ability. In addition, the impairment of cholinergic system or imbalance between dopaminergic system and cholinergic system also
plays a role in the pathophysiology of PD, especially, Parkinson's disease
dementia (PD dementia, PDD). A large number of animal experiments and
clinically studies showed that change in the cholinergic system is closely
related to learning and memory. Cholinergic neuronal degeneration may be associated with attention disorders and executive function decline in PD. α-synuclein is the first PD gene and the mutation of α-synuclein has been linked to a variety of neurological disorders including PD and

PDD. Recently, α-synuclein aggregates were found to locate at the presynapses and cause synaptic dysfunction, suggesting presynaptic neurotransmitter deficiencies in Parkinson's disease, PDD and DLB. Drosophila has been widely used as a system to study neurobiology, neuropharmacology, and neuropathologic mechanisms. The projection neurons (PNs) play a critical role in learning and memory in drosophila. PNs are cholinergic neurons and are projected to mushroom body to receive cholinergic synaptic transmission from the olfactory bulbs and transduct to higher brain center. In the present study, compared with non-transfected controls, the ability of learning and memory of α-synuclein wild type and A53Tflies significantly decreased. The miniature excitatory postsynaptic currents (mEPSCs) frequency but not mean mEPSCs amplitude was also significantly lower in the α-synuclein WT and A53T flies than in the control flies. Additionally, there was a significant decrease in the calcium currents of PNs in both α-synuclein wild type and A53T flies compared with control flies.
All together, our data suggest that overexpression ofα-synuclein impair learning and memory and cholinergic mini-synaptic currents and block the calcium current of PNs in Drosophila.

Abstract: Parkinson’s disease (PD) is characterized by degenerative motor symptoms including resting tremor and bradykinesia. Mutations in the human α-synuclein gene lead to early onset PD making these mutations attractive targets for the design of mouse models of PD; however, phenotypes of α-synuclein mutant mice vary depending upon which promoter is used to drive transgene expression. The goal of this work was to characterize the onset and progression of behavioral symptoms and neurochemical alterations in transgenic mice expressing mutant (A53T) human α-synuclein controlled by a Thy-1 promoter. We used the line of A53T (SNCA)

mice originally described by (Chandra et al., 2005; Cell 123:383-396); the SNCA mice and wild type (WT) mice of the same genetic background were purchased from Jackson Labs and used in separate cohorts to evaluate behavioral function (n=16 WT; n=12 SNCA) and for biochemical analysis (n=30 WT; n=30 SNCA). Beginning at 8 weeks of age, mice were evaluated for motor function (rotarod and stride length) and anxiety (elevated plus maze and open field) every 2 weeks until 32 weeks of age. At 24 weeks mice were evaluated in a Continuous Lab Animal Monitoring System (CLAMS). For biochemical analysis, a separate cohort of mice was euthanized at 12, 24 and 36 weeks for: immunoblot analysis of α-synuclein, dopamine transporter (DAT), tyrosine hydroxylase (TH); ELISA of brain-derived neurotrophic factor (BDNF) (n=4 WT; n=4 SNCA); and HPLC analysis of monoamine neurotransmitters (n=6 WT; n=6 SNCA). Behaviorally, SNCA mice display consistent motor and anxiety symptoms that do not worsen over time. Rotarod and stride length analyses revealed significant motor deficits at 8-11 weeks of age and anxiety tests showed a decrease in anxiety in SNCA mice compared to littermates, consistent with other reports of mouse models of PD. CLAMS analysis revealed an increase in activity during the dark phase for SNCA mice compared to WT and a reduction in overall sleep time for SNCA mice at 6 months of age consistent with clinical reports of sleep abnormalities in PD. Changes in the expression of DAT and neurotransmitters appeared early (12 weeks) in the striatum and late (36 weeks) in the midbrain. An early rise in dopamine was associated with a rise in BNDF implying a compensatory mechanism. Increases in serotonin levels potentially explain reductions in anxiety behaviors. Results indicate that this model of PD displays consistent and relevant motor, anxiety and sleep phenotypes. Neurotransmitter data are among the first of its kind to profile longitudinal alterations in neurotransmitters in PD mice and indicate that alterations begin in the striatum and progress to the midbrain.

Title: Reduced hippocampal theta frequency in mice expressing the human A53T mutation of alpha-synuclein

Authors: E. MOROZOVA[1], J. DUNLOP[1], *M. HAJOS[2,1]
[1]Pfizer, Inc, Groton, CT; [2]Comparative Med., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Abnormal hyperphosphorylation and aggregation of pathogenic proteins are common features of various neurodegenerative disorders. Aggregated fibrillar α-synuclein, a presynaptic protein is a major component of Lewy bodies is thought to play a critical role in pathology of Parkinson's disease. It is known that A53T form of α-synuclein, which is associated with autosomal dominantly inherited form of Parkinson's disease have a high rate of self-aggregation, supporting this notion. The A53T transgenic mice express the human A53T alpha-synuclein variant (full-length, 140 amino acid isoform) directed by the mouse prion promoter (Giasson et al., 2002), leading to the formation of filamentous neuronal inclusions and neurodegeneration, providing an experimental tool for studying pathophysiological mechanisms underlying Parkinson's disease.

In the present experiments the impact of over-expression of alpha-synuclein on hippocampal physiology was studied in 8 month old, homozygous, male A53T transgenic and age matched wild-type control mice. Local field potentials were recorded in the hippocampus CA1 region and elicited theta oscillation recorded in response to high-frequency electrical stimulation of the brainstem nucleus pontis oralis (nPO) under urethane anesthesia. Hippocampal recordings showed a current-dependent increase in power and frequency of theta oscillation in response to stimulation of the nPO in wild-type mice. A53T transgenic mice showed a significant decreased peak frequency across the entire theta frequency range (4-9 Hz) in response to increasing stimulating current comparing to wild-type control mice. In contrast, there was no significant difference in absolute and relative theta power between A53T transgenic and control mice. Reduced frequency in elicited theta oscillation has been well characterized following administration of various anxiolytic drugs (McNaughton et al., 2007); therefore the currently described hippocampal activity of A53T transgenic mice could indicate their well characterized diminished anxiety. Furthermore, the neuroaxis involved in generation of stimulation-induced hippocampal theta oscillation also contributes to rapid eye movement (REM) sleep regulation. Alterations in elicited hippocampal oscillation predict changes in REM sleep physiology, which is known to be impacted in Parkinson's disease patients at the early stage of the disease.

Title: Comparison of D-amphetamine -induced locomotor activity and brain alpha-synuclein load in two mouse strains carrying A30P alpha-synuclein

Authors: *M. H. PILTONEN, M. SAVOLAINEN, T. T. MYÖHÄNEN, P. T. MÄNNISTÖ
Div. of Pharmacol. & Toxicol., Univ. of Helsinki, Helsinki, Finland

Abstract: Alpha-synuclein (aSyn) is coded by the SNCA -gene, and a missense mutation switching Ala30 residue to Pro (A30P) has been shown to be strongly associated with an autosomal dominant familial form of Parkinson's disease (PD). The mutation is located in the amphipathic N-terminal domain of the protein, which couples the protein with phospholipid membranes. The A30P -mutated protein has enhanced propensity to form oligomers and aggregates, and decreased connection with lipids. Transgenic mouse lines have been created in attempt to model PD, but no consistent results have been obtained. Some strains exhibit generally age-dependent motor defects, but pathology of the dopaminergic system is rare. Also, while one A30P-transgenic strain is more sensitive to the effects of the dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, another strain does not show any sensitization. Despite contradictory data, expression of human A30P aSyn in mice can lead to neuropathological and behavioral changes. We have studied D-amphetamine -induced locomotor activity and brain aSyn load in two A30P -strains: one with inserted human A30P gene (mPrPh(A30P)asyn), and another one with an A30P-point mutated mouse aSyn gene (SNCA(A30P)). We found a significantly decreased response to 1 mg/kg D-amphetamine in the mPrPh(A30P)asyn-mutated mice when compared to wild-type (WT) littermates, which may be due to a lower capacity or inadequate recruitment of dopamine storage pool as earlier reported. The decrease was not seen in SNCA(A30P)-strain, whose mutant mice rather exhibited slight hyperactivity. With 2.5 mg/kg of D-amphetamine, no differences were observed between genotypes in either of the strains. Immunohistochemical staining of aSyn revealed a significant accumulation of aSyn in the substantia nigra, striatum and M1 motor cortex in the mPrPh(A30P)asyn mutant mice when compared to WT mice, but in SNCA(A30P) -mice the accumulation was less apparent. This is most likely due to the different total amounts of aSyn expressed by the strains, which may also partially explain the more robust behavioural changes in mPrPh(A30P)asyn -mice.

Title: Prolyl oligopeptidase inhibitor KYP-2047 reduces α-synuclein aggregation in rotenone treated α-synuclein overexpressing cell lines

Authors: *M. J. HANNULA[1], L. DOKLEJA[1], M. GERARD[2], V. BAEKELANDT[3], P. T. MÄNNISTÖ[1], T. T. MYÖHÄNEN[1]
[1]Pharmacol. and toxicology, Univ. of Helsinki, Helsinki, Finland; [2]Lab. of Biochem., Katholieke Univ., Leuven-Kortrijk, Belgium; [3]Lab. of Neurobio. and Gene Therapy, Div. of Mol. Med., Katholieke Univ., Leuven, Belgium

Abstract: Prolyl oligopeptidase (PREP) is an enzyme hydrolyzing peptides less than 30 amino acids. It is present in many different species and, in mammals, it is widely distributed in the tissues. Its physiological function is still unclear but present hypothesis suggests, that the role of PREP is to cleave neuropeptides including substance P, vasopressin and neurotensin. Recently, it was shown that PREP accelerates the aggregation of wild-type α-synuclein (α-syn) under cell-free conditions, and this action can be blocked with PREP inhibitors. Abnormal misfolding of α-syn is considered to be the most critical pathogenic event leading to neurodegeneration in Parkinson's disease (PD). Mutations in α-syn gene, such as, A30P, A53T and E46K point mutations, lead to increased accumulation of α-syn in cells and to early onset PD.
We treated SH-SY5Y cell lines overexpressing A30P or A53T mutant human α-syn with rotenone to study the effect of PREP inhibitor KYP-2047 on α-syn aggregation in cell culture. Wild type SH-SY5Y cells served as control. Roteone is an organic pesticide that causes mitochondrial dysfunction by inhibiting complex I of the electron transport chain. This leads to energy deficiency, aggregation of α-syn and to selective death of dopaminergic cells.
Cells were exposed to rotenone (50 nm) for 3 days to induce α-syn aggregation and were then treated with the PREP inhibitor (10 μm) during or after the stress. The aggregation and immunoreactive protein of α-syn were determined by immunohistochemistry and western blot. The effect of KYP-2047 on cell viability was investigated and double-label immunostaining with confocal microscopy was used to study the colocalization between PREP and α-syn.
Rotenone induced robust α-syn aggregation in both α-syn overexpressing cell lines, and low concentrations of KYP-2047 significantly reduced the number of cells with α-syn inclusions and abolished the colocalization of α-syn and PREP. KYP-2047 significantly reduced the amount of aggregated α-syn, and it had beneficial effects on cell viability.
These results show rotenone to be capable of modeling one of the main features of PD, aggregation of α-syn, in α-syn overexpressing cell lines. Results also suggest that PREP may

play role in brain accumulation and aggregation of α-syn, while KYP-2047 seems to effectively prevent these processes.

Title: Prolyl oligopeptidase inhibitor KYP-2047 reduces the high molecular weight α-synuclein forms in the brain of α-synuclein A30P mouse strain

Authors: *M. H. SAVOLAINEN[1], V. BAEKELANDT[2], P. T. MÄNNISTÖ[1], T. T. MYÖHÄNEN[1]
[1]Div. of Pharmacol. and Toxicology, Univ. of Helsinki, Helsinki, Finland; [2]Lab. of Neurobio. and Gene Therapy, K.U. Leuven, Leuven, Belgium

Abstract: α-Synuclein is natively unfolded, abundant brain protein that consists of 140 amino acids. α-Synuclein is believed to have a physiological role in dopamine transport, storage and release but its aggregation is toxic. The hallmark findings of the brain of patients with Parkinson’s disease are α-synuclein rich inclusions called Lewy bodies. Inherited early-onset forms of Parkinson’s disease are strongly associated with autosomal mutations A30P, A53T and E46K in α-synuclein coding gene or its duplications or triplications. Prolyl oligopeptidase (PREP) is a serine protease cleaving proline-containing neuropeptides shorter than 30 amino acids. PREP has been found to accelerate α-synuclein aggregation in vitro although it cannot cleave it. Recent studies have shown that a PREP inhibitor treatment reduces aggregation of α-synulein in vitro and in vivo.
The effect of a PREP inhibitor, KYP-2047, on α-synuclein aggregation and accumulation in vivo was further studied using a transgenic knock-in mouse model. Mice had an inserted A30P point mutation on their α-synuclein gene. It has been reported earlier that mice develop age related decline in motor function. KYP-2047 was administered subchronically for five days or chronically for 28 days period intraperitoneally using Alzet® osmotic pumps. α-Synuclein

immunohistochemistry and Western blot analysis were done to study α-synuclein amounts in the brain after the treatments. The fractionation method was used to separate different molecular weight forms of α-synuclein.
After the 5- and 28- days KYP-2047 treatments of the A30P +/+ transgenic mice we observed a decrease in α-synuclein immunostaining in different brain areas (substantia nigra, cortex and striatum) compared to the vehicle treated animals. No effect was seen in wild type littermates. In Western blot analysis the protein levels of high molecular weight α-synuclein aggregates in the A30P +/+ mice were decreased in KYP-2047 treated compared to the vehicle treatment.
The formation of aggregates of α-synuclein is a key step in Parkinson's disease pathophysiology. PREP inhibitor, KYP-2047, decreases the amount of aggregated form of A30P- α-synuclein in the mouse brain. This may offer a new principle for therapeutic applications in Parkinson's disease.

Title: RING finger protein 11 (RNF11) mediates inflammatory responses and alpha-synuclein-induced neurodegeneration in *Drosophila*

Authors: *E. L. PRANSKI[1,2], J. J. LAH[1,2], A. I. LEVEY[1,2], S. SANYAL[2,3], R. S. BETARBET[1,2]

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disorder that is characterized by loss of dopaminergic neurons in the substantia nigra and the presence of Lewy bodies in surviving neurons. RING finger protein 11 (RNF11), a candidate gene at the PARK 10 locus, has been recently reported to be a negative regulator of the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) signaling. NF-κB is a critical regulator

of inflammation and apoptosis and thus is a key player in chronic inflammation, pathogenesis and progression of various neurodegenerative diseases including PD. The function of NF-κB pathway is well conserved and plays a major role in Drosophila immune response, including the Toll and the immune deficiency (Imd) pathways. In this study, we report the first characterization of CG32850, the Drosophila homologue of RNF11 (dRNF11), as a key regulator of Drosophila immune response signaling cascade, as well as dRNF11's role in mediating neurodegeneration in a Drosophila model of PD. To characterize dRNF11, classical infection paradigms with gram-positive and gram-negative bacteria were performed to induce activation of Toll and Imd pathways respectively. Quantitative real-time PCR was used to measure mRNA levels of antimicrobial peptides at various time points post-infection as a direct measure of immune pathway activation. Through genetic manipulation of RNF11 expression, we demonstrate that dRNF11 is indeed a negative regulator of the Drosophila immune response and knockdown of dRNF11 leads to heightened immune responses with decreased survival. Next, we examined the role of dRNF11 in a genetic model of PD where wild-type or mutant alpha-synuclein is over-expressed. This model is characterized by adult-onset loss of dopaminergic neurons, alpha-synuclein inclusions, and locomotor deficits. Expression of dRNF11 and alpha-synuclein was targeted to the eye in order to easily screen for potential interactions leading to eye degeneration phenotypes. We observe neurodegeneration in the eyes of adult animals expressing alpha-synuclein, with enhanced degeneration observed in conjunction with knockdown of dRNF11. Further experiments are being pursued to identify the contribution of immune activation in this phenotype. These findings support the hypothesis that in Drosophila, dRNF11 negatively regulates immune activation and fly survival and that reduced or functionally compromised RNF11 can exacerbate alpha-synuclein-induced neurodegeneration, a phenomenon with known implications in PD-like neurodegenerative disease pathogenesis and progression.

Title: Neuronal RING finger protein 11 (RNF11) modulates susceptibility to 6-OHDA-induced nigral degeneration and behavioral deficits

Authors: *R. BETARBET[1,2], N. DALAL[2,1], J. HERSKOWITZ[2,1], C. LAZO[1,3], G. MILLER[1,3], J. LAH[1,2], A. LEVEY[1,2], E. PRANSKI[1,2]

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disorder characterized by selective loss of dopaminergic (DA) neurons in substantia nigra (SN) and presence of Lewy bodies in cytoplasm of surviving neurons. We have previously demonstrated that RING finger protein 11 (RNF11), a candidate gene at the PARK 10 locus, is localized to cortical and nigral Lewy bodies in PD brain tissue. Additionally, we have reported neuronal RNF11 as a negative regulator of the NF-κB signaling pathway. A number of studies have highlighted chronic inflammation, through activation of NF-kB pathway, as a key player in progressive pathogenesis of PD. In this report, we determined if RNF11-mediated modulation of neuronal NF-kB signaling had an impact on 6-hydroxydopamine (6-OHDA)-induced behavioral deficits and DA neuron loss associated with this rodent model of PD. In vivo levels of neuronal RNF11 were manipulated by targeted knockdown (KD) or over-expression (OE) of RNF11 in the SN through unilateral stereotaxic injections of tagged adeno-associated virus (AAV2) constructs. After 2 weeks, rats received striatal stereotaxic injections of 6-OHDA on the same side. Amphetamine-induced rotation was monitored at 3 weeks post-6-OHDA lesion. Brains were harvested 4 weeks post-6-OHDA lesion to determine the role of RNF11 on neurodegeneration using immunohistochemical and quantitative real-time PCR analysis. Nigral DA neuron counts were estimated using stereological analyses of tyrosine hydroxylase (TH)-positive neurons in SN. Additionally, mRNA expression levels of RNF11, TH, and inflammatory markers were measured from microdissected ventral midbrain (VM) regions. For quantitative analysis, the uninjected side served as an internal control for each animal. AAV2 constructs specifically infected neurons at the site of injection. Targeted OE of neuronal RNF11 in SN decreased NF-kB and TNF-alpha mRNA levels in VM samples when compared to scramble-injected samples, and resulted in significant increase in amphetamine rotations & more extensive 6-OHDA-induced DA loss. In converse, KD of neuronal RNF11 correlated with increase in NF-kB and TNF-alpha mRNA levels in VM samples and protected against 6-OHDA-induced DA loss & reduced amphetamine rotations. These findings demonstrate that neuronal RNF11 negatively regulates canonical NF-κB signaling in vivo and that chronic activation of neuronal NF-kB is neuroprotective. In contrast, others have reported glial activation of NF-kB to enhance neurodegeneration. This diverse role of NF-kB within the brain has important implications for targeted therapeutics aimed at controlling neuroinflammation and neurodegeneration.

Title: Phenothiazine analogues as potential α-synuclein imaging ligands for Parkinson's Disease: Synthesis and evaluation of binding affinity for α-synuclein fibrils using a fluorescence assay

Authors: *P. T. KOTZBAUER[1], L. YU[2], J. CUI[2], P. PADAKANTI[2], L. A. ENGEL[1], D. P. BAGCHI[1], Z. TU[2]

Abstract: Accumulation of misfolded, fibrillar α-synuclein (α-syn) in Lewy bodies and Lewy neurites is the pathological hallmark of Parkinson's Disease (PD). Ligands with high affinity for α-syn fibrils could be utilized as imaging agents to improve the diagnosis of PD and to monitor disease progression. To identify ligands that have high binding potency toward aggregated α-syn, we synthesized a series of phenothiazine derivatives and assessed their binding affinity to recombinant α-syn fibrils using a fluorescence assay. The binding affinity of phenothiazine compounds for fibrils was determined based on competitive binding with the fluorescent compound Thioflavin T (ThioT), after determination of the K_d for ThioT binding in saturation binding studies. In the ThioT competitive binding assay, increasing concentrations of phenothiazine compounds were added to binding reactions containing ThioT and α-syn fibrils. Among 16 new analogues, the competitive binding results indicate that compound **11b** has high affinity to α-syn fibrils (K_i = 32.10 ± 1.25 nM) and compounds **11d**, **16a** and**16b** have moderate affinity to α-syn fibrils ($K_i \approx$ 50 to 100 nM). Several of these compounds are suitable for synthesis of radiolabeled ligands to further evaluate binding affinity and selectivity, including

[^{11}C]**11b,** [^{18}F]**16a, and [^{125}I]16b.** Further optimization of the structure of these analogues may yield compounds with high affinity and selectivity for aggregated α-syn. A high affinity synuclein imaging ligand suitable for quantifying the distribution of fibrillar α-syn *in vivo* could improve diagnostic accuracy and could also improve the understanding of disease progression in PD.

Title: Binding of the alpha-synuclein radioligand Synuclein Imaging Ligand 23 (SIL23) and related analogues reflects the level of fibrillar α-synuclein in Parkinson's Disease brain tissue

Authors: *D. BAGCHI[1], M. UDAN-JOHNS[1], L. YU[2], R. H. MACH[2], Z. TU[2], P. T. KOTZBAUER[1]
[1]Neurol., [2]Radiology, Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Accumulation of misfolded, fibrillar α-synuclein (α-syn) in Lewy bodies and Lewy neurites is the pathological hallmark of Parkinson's disease (PD). Ligands with a high affinity for α-syn fibrils could be utilized as imaging agents to improve the accuracy of clinical diagnosis of PD, which may become increasingly valuable as disease modifying therapies are developed. Additionally, quantifying the distribution of pathological α-syn *in vivo* could improve understanding and assessment of disease progression, including the onset of dementia in PD patients. We previously identified a group of phenothiazine derivatives that bind α-syn fibrils. To further characterize the potential utility of this compound class as radiotracers, we synthesized the ^{125}I-labeled phenothiazine analogue Synuclein Imaging Ligand (SIL23) and characterized its affinity and specificity for the pathological form of α-syn. Radioligand binding studies demonstrated that SIL23 has moderately high binding affinity for fibrils prepared from recombinant α-syn (K_d 140 nM, B_{max} 5 pmol/nmol α-syn monomer) and that it has relative selectivity for α-syn fibrils over other amyloid fibrils, with 5 fold lower affinity for $A\beta_{1-42}$ fibrils

and 2 fold lower affinity for tau fibrils. An additional phenothiazine analogue, SIL26, has a K_i of 15 nM, with more than 5 fold selectivity for both Aβ and tau fibrils. Binding studies also demonstrated that a 140 nM SIL23 binding site is present in the insoluble fraction from PD postmortem brain tissue but not control tissue and that the density of SIL23 binding sites is comparable to binding site densities for amyloid Aβ tracers in Alzheimer's disease. These results define a radioligand binding site on α-syn fibrils that is specifically present in PD brain tissue and that can be feasibly targeted to quantify pathological α-syn accumulation *in vivo*. Further optimization of the binding affinity and selectivity of SIL23 analogues could yield a radiotracer that can be used to improve diagnostic accuracy and monitor disease progression in PD, and could facilitate the evaluation of new therapeutic approaches.

Abstract: Alpha-synuclein (alpha-syn) is an abundant neuronal protein that has been linked to neurodegeneration in both sporadic and familial forms of Parkinson's disease (PD). Mutations, duplications and triplications in the gene encoding alpha-syn are responsible for earlier forms of PD. Moreover, aggregated alpha-syn, which is a major component of Lewy bodies, alpha-syn post-translational modifications, mitochondrial dysfunction and oxidative stress have also been pointed as key pathogenic events of this disorder. In this study we analysed the link between

oxidative stress and alpha-syn phosphorylation at Ser129 in SH-SY5Y neuroblastoma cell lines overexpressing wild-type (WT) and mutant A53T alpha-syn, either transiently transfected (in the case of WT versus A53T alpha-syn, linked to GFP) or conditionally expressing (in the case of WT protein only) in a system regulated by doxycycline (-Dox). Oxidative stress induced with ferrous iron ($FeSO_4$) was shown to increase the production of reactive oxygen species (ROS), namely hydroperoxides and superoxide anion. In transiently transfected cells, iron-induced ROS was correlated with the formation of ubiquitin-labelled alpha-syn aggregates, mitochondrial depolarization and phosphorylation of alpha-syn at Ser129. Furthermore, we reported a higher susceptibility of mutant A53T alpha-syn expressing cells. In SH-SY5Y cells conditionally overexpressing alpha-syn increased ROS was observed under basal conditions in cells overexpressing alpha-syn, compared to cells expressing the endogenous protein (+Dox), which was exacerbated by iron exposure. Analysis of cellular antioxidants activity revealed a decrease in superoxide dismutase (SOD)1 under basal conditions in -Dox cells (in total and mitochondrial fractions), whereas SOD2 activity was increased in mitochondria upon exposure to iron, an effect that was significant in -Dox cells. Moreover, GSH and GSSG levels diminished in -Dox cells under basal conditions, in total or mitochondrial fractions, which may explain the increase in ROS. Accordingly, the levels of glutamate-cysteine ligase catalytic subunit (GCLc) were also decreased in -Dox cells, accompanied by a decrease in the activity of enzymes of glutathione synthesis. Interestingly, preliminary data support an increase in alpha-syn phosphorylation at Ser129 in -Dox cells. Overall, data suggest that overexpression of alpha-syn may be involved in modifying the susceptibility to oxidative stress and the antioxidant response, defining subsequent alpha-syn aggregation and phosphorylation in agreement with the pathological events described in PD.

Title: Effects of S129 phosphorylation on alpha-synuclein self-assembly and membrane binding

Authors: *F. SAMUEL, V. NG, P. E. FRASER, C. B. COLE, P. E. FRASER, A. TANDON
Tanz CRND, Univ. of Toronto, Toronto, ON, Canada

Abstract: α-Synuclein (α-syn) is a highly abundant presynaptic protein that exists as membrane-bound and freely-diffusible cytosolic. In normal brains, less than 5% of α-syn is phosphorylated at serine residue 129 (pS129), whereas nearly 90% of the α-syn in Parkinson disease Lewy bodies (LB) is phosphorylated at S129. To further clarify the relationship between S129 phosphorylation and the biophysical and biological properties of α-syn, we generated recombinant α-syn with and without pS129. To do this, we used *E. coli* to express human α-syn with and without polo-like-kinase 2 (PLK2), a major kinase responsible for S129 phosphorylation. Mass spectrometric and western blot analyses revealed complete S129 phosphorylation when α-syn and PLK2 were co-expressed versus the absence of pS129 when α-syn was expressed alone. Structural properties of non-phosphorylated and phosphorylated forms of α-syn were then assessed by circular dichroism spectra and electron microscopy. Our results suggest that serine phosphorylation accelerated the conversion of wild-type α-syn secondary structure from random coil to beta sheet, as well as fibril formation. Moreover, the presence of PD-linked mutations, A53T and A30P, further increased the self-assembly of the pS129 α-syn. We also assessed whether pS129 affected the binding of α-syn to synaptosome membranes. Although, S129 phosphorylation had little effect on the WT α-syn membrane binding, it appeared to increase association of A30P α-syn and decrease that of A53T α-syn. Overall, our results indicate that aberrant S129 phosphorylation modifies α-syn structure and its self-assembly, and differentially impacts α-syn mutant binding to presynaptic membranes.

Abstract: α-Synuclein is normally a soluble presynaptic protein, but it also has an intrinsic ability to aggregate and form 10-15nm amyloidgenic fibrils, which are the major component of Lewy bodies and Lewy neurites. These Lewy pathologies are a defining hallmark of Parkinson's disease (PD) and several recent findings suggest that α-synuclein aggregate formation may proceed through a seeded prion-like mechanism, but this has not been formally proven as other alternative mechanisms may also explain these observations. Furthermore, aggregation of α-synuclein may propagate in vivo through glia. α-Synuclein fibrils can be taken up by cultured cells leading to the seeded formation of cytoplasmic inclusions, similar to those seen in PD. In primary neuronal culture, we have been able to seed the formation of α-synuclein inclusions, similar to Lewy body pathology, using in vitro fibrilized protein. However, inclusion formation in our primary cultures occurs mainly in astrocytes and is associated with changes in astrocytic morphology and cytokine secretion profiles. Similarly, preformed α-synuclein fibrils can also induce the formation of α-synuclein inclusions in the brain of mice. These inclusions are predominantly found in neurons and can be induced in various areas of the brain. Fibrillar α-synuclein-induced brain pathology is associated with massive astrogliosis and microgliosis. Collectively, these findings show that α-synuclein is capable of inducing its own inclusion formation, and that the process is associated with an immune response.

Title: AMPK over-activation leads to accumulation of alpha-synuclein oligomers and decrease of neurites

Authors: *P. JIANG, M. GAN, A. EBRAHIM, M. CASTANEDES-CASEY, D. DICKSON, S.-H. YEN
Neurosci., Mayo Clin. Col. of Med., JACKSONVILLE, FL

Abstract: Parkinson disease (PD) is an age-related neurodegenerative disorder characterized pathologically by abnormal deposition of filamentous α-synuclein (α-syn) as Lewy bodies and Lewy neurites. Increased α-syn expression can occur in brains of aging human and neurotoxin (e.g. MPTP) treated mice. Since previous studies have shown increased brain lactate levels in aging brains, in PD affected subjects when compared to age-matched controls, and in mice treated with MPTP, we tested the effect of lactate exposure on α-syn in a cell based-study. We demonstrated that (i) lactate treatment led to α-syn accumulation and oligomerization in a time- and concentration-dependent manner, (ii) such alterations were mediated via adenosine-monophosphate activated protein kinase (AMPK) and associated with increases of cytoplasmic phosphorylated AMPK levels, (iii) AMPK activation facilitated α-syn accumulation and phosphorylation at Ser129, (iv) lactate treatment or overexpression of active AMPK decreased α-syn turnover, and (v) Lewy body-bearing neurons displayed abnormal cytoplasmic distribution of phosphorylated AMPK, which normally is located in nuclei. Together, our results suggest that chronic α-syn accumulation in neurons induced by lactate-triggered AMPK activation in aging brains may be a novel mechanism underlying α-synucleionpathies in PD and related disorders.

Title: AAV-alpha-synuclein-induced overexpression as rat model to investigate olfactory dysfunction and disease modification in Parkinson’s disease

Authors: *P. VOEHRINGER, B. FERGER
CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany

Abstract: Parkinson's disease (PD) is a common progressive neurodegenerative movement disorder, which is characterized by a severe loss of nigrostriatal dopaminergic neurons and accumulation of aggregated alpha-synuclein (alpha-syn) in neurons of the central and peripheral nervous system. Moreover, olfactory dysfunction is a frequent non-motor symptom of PD and is considered as a potential biomarker for preclinical PD even before onset of motor impairment. Here, we used the AAV-alpha-syn-WT overexpression model to mimic motor and non-motor symptoms of PD in rats. Nigral injection of AAV-alpha-syn-WT resulted in severe motor

disturbances accompanied by dopamine (DA) depletion in the striatum and loss of tyrosine hydroxylase (TH) positive neurons in the substantia nigra pars compacta (SNpc). Additionally, by injecting AAV-alpha-syn-WT into the bulbus olfactorius of rats, we were able to induce olfactory impairments measured by a buried food pellet test.
In conclusion, we showed that the AAV-alpha-syn rat model is suitable for the recapitulation not only of motor impairments but also of early symptoms in the pathogenesis of PD such as olfactory dysfunction. Treatment of olfactory dysfunction in a rodent animal model of PD could be important to identify novel mechanisms for disease modification and biomarker studies in PD.

Title: Rab protein expression mediates alpha-synuclein oligomer formation and cytotoxicity

Authors: *N. R. MCFARLAND[1], T. SAHARA[1], L. KIBUUKA[2]
[1]Neurol., Univ. of Florida, Col. of Med., Gainesville, FL; [2]Alpert Med. Sch., Brown Univ., Providence, RI

Abstract: Abnormal accumulation and deposition of α-synuclein (αsyn) have been implicated in intracellular stress, vesicle trafficking deficits, and cytotoxicity, suggesting a pathogenic mechanism for Parkinsonism. Recent data in several PD models, including yeast, primary cultures, C. elegans, and Drosophila, demonstrate that expression of specific Rab proteins ameliorate toxicity and trafficking deficits as a result of αsyn over-expression, suggesting that abnormal accumulation of αsyn may interfere with normal Rab protein function. Rab proteins may also play a role in protecting against αsyn toxicity and vesicle accumulation. We hypothesized that one potential role of Rabs may be to prevent abnormal αsyn accumulation and formation of “toxic” oligomeric species. We thus
examined the effects of specific Rab proteins, including mouse Rab1, its human paralog Rab8A, and Rab 3A, on αsyn dependent toxicity and oligomer formation in an H4 neuroglioma cell model. Flag-tagged Rab protein sequences were cloned into a pcDNA vector. We then transiently co-transfected H4 cells with human wt αsyn and Rabs, and measured cytoxicity at 36-

48 hours. To examine the effects of Rab proteins on αsyn oligomer formation and toxicity, we utilized a protein complementation assay employing constructs with αsyn fused to N and C-terminal fragments of the Gaussian luciferase molecule (or Venus-YFP). Luciferase fragments alone are not active, but when brought together by αsyn interactions reconstitute their bioluminescent activity. Rab proteins co-expressed with Syn-luciferase N and C-terminal fragments significantly (p=.024) reduced luciferase activity compared to empty vector control. Both Rab1 and Rab8A had greater, but non-significant, effects compared to Rab3A. Consistent with these findings, native Western blot analysis of cell extracts also showed a reduction in high-molecular weight αsyn species, suggesting expression of these Rabs decreases αSyn interactions and high-molecular weight oligomer species. Size-exclusion data similarly shows a shift toward smaller αsyn species, and provide further support that specific Rab proteins reduce αsyn oligomer species. Samples run under fully denatured conditions indicated no change in total αsyn expression as a result of Rabs. These data suggest that Rabs alter αsyn oligomer, rather than total αsyn levels, either through enhanced degradation or reduction in αsyn-αsyn interactions. These findings provide evidence that Rab proteins may be important mediators of αsyn accumulation and toxicity through possible reduction of toxic oligomeric species.

Abstract: Pathologic, biochemical, and imaging studies indicate a significant degree of degeneration of the serotonin (5-HT) system in Parkinson's disease (PD), which may contribute to some of the non-motor symptoms of the disease. However, reports of 5-HT neurons in toxin-based models of PD have been inconsistent. Differences in toxin use and administration regimen, animal species, and quantitative assessment of neuronal loss may account for these inconsistencies. The goal of the present study was to assess the state of the 5-HT system in a monkey model that mimics the slow and progressive degeneration that occurs in idiopathic PD. Adult Rhesus monkeys were treated with weekly injections of MPTP (n=3, 0.2-0.5 mg/kg, i.m.) for 21 weeks, leading to progressive development of parkinsonian symptoms. Postmortem 5-HT immunohistochemistry and stereological cell count revealed ~80% loss of 5-HT terminals in the striatum and ~35% loss of neuronal cell bodies in the dorsal raphe ($P<0.001$) in MPTP-treated monkeys compared with control. Furthermore, taking into consideration the functional expression of metabotropic glutamate receptor 5 (mGluR5) in 5-HT cells (Bradbury et al., 2003, Neuropharmacology 44: 562), we sought to determine whether treatment with an mGluR5 antagonist could protect 5-HT neurons from degeneration in MPTP-treated monkeys. To address this issue, the highly specific mGluR5 antagonist,3-[(2-methyl-1,3-thiazol-4-yl) ethynyl] pyridine (MTEP) was administered daily (10 mg/kg i.m.) in 4 additional MPTP-treated monkeys. Densitometry measurements revealed a significant preservation of the striatal 5-HT innervation in MPTP/MTEP-treated monkeys (~10% loss from controls) compared with MPTP/vehicle-treated animals (~80% loss from controls). Stereological cell counts of 5-HT-positive neurons in the dorsal raphe are in progress to determine if MTEP also protects 5-HT cell bodies from degeneration in this nonhuman primate model of PD. Together with our recent findings (Masilamoni et al., 2011, Brain 134:2057), the available data suggest that MTEP protects against degeneration of dopaminergic, noradrenergic and 5-HT cells in MPTP-treated monkeys, adding to the potential relevance of mGluR5 antagonists as neuroprotective agents in PD.

Title: Overexpression of endogenous GDNF in natively expressing cells increases cell numbers and dopamine levels in the nigrostriatal system

Authors: *J. J. KOPRA[1], J.-O. ANDRESSOO[2], J. MIJATOVIC[1], C. AMBERG[2], N. PULKKINEN[1], P. PIEPPONEN[1], M. SAARMA[2]

Abstract: Glial cell line-Derived Neurotrophic Factor (GDNF) protects and promotes the survival of embryonic dopamine (DA) neurons in vitro, whereas exogenous and viral vector-induced overexpression of GDNF have been shown to promote survival of midbrain DAergic neurons in vivo against neurotoxic insults. However, the role of endogenous GDNF signaling in the normal function and maintenance of nigrostriatal DAergic neurons remains unclear. To study the effect of increased endogenous GDNF in the development and function of nigrostriatal dopaminergic system, we created a knock-in, hypermorphic mouse model that is overexpressing physiological GDNF in natively GDNF-producing cells under physiological promoter. Heterozygous (hetz) and homozygous (homoz) hypermorphic mice have 30 % and 70 % increased brain GDNF levels, respectively, compared to wt. Hetz mice are viable until at least 17 months of age, whereas homoz mice die by P10, because of kidney failure. We estimated the number of dopaminergic cells in substantia nigra pars compacta with stereological microscopy in the age groups of 7.5 days and 3 months by using TH- and VMAT2-stainings. We also measured the striatal tissue levels of DA and its metabolites with HPLC in the age groups of 7.5 days, 4 months and 17 months. Finally we measured amphetamine (1 mg/kg) induced locomotor activity, and striatal DA response to local amphetamine stimulation (100 µM for 1 hour) using in vivo microdialysis in freely moving animals. We found a 15 % increase in DAergic cell number at the age of P7.5 in both hetz and homoz hypermorphic mice. This increase was retained until 3 months between wt and hetz mice. Also the striatal levels of DA were increased (20 %) at P7.5 equally in both genotypes. This increase also persisted until adulthood and old age. Amphetamine-induced locomotor activity and striatal DA response were augmented by about 30 % in hetz mice as compared to wt. In conclusion, our results demonstrate that already a modest increase in the expression of endogenous GDNF in the naturally GDNF expressing cells functionally enhances the nigrostriatal DAergic system in vivo with persistent changes until old age.

Title: BDNF receptor is involved in the beneficial effects of exercise in hemi-parkinsonians rats.

Authors: *C. C. REAL[1], A. F. B. FERREIRA[1], G. P. CHAVES-KIRSTEN[1], A. S. TORRÃO[1], R. S. PIRES[2], L. R. G. BRITTO[1]
[1]FISIOLOGIA E BIOFÍSICA, ICB/USP, SAO PAULO, Brazil; [2]UNICID, Physical Therapy Graduate Program, Brazil

Abstract: Parkinson disease (PD) is the focus of intense research of possible strategies for its treatment and prevention. Physical exercise is known to produce beneficial effects to the nervous system, and, in most cases, brain-derived neurotrophic factor (BDNF) appears to be involved in such effects. Our aim was to investigate the role of BDNF in the treadmill exercise-induced histological/neurochemical and behavioral changes in a rat model of unilateral PD induced by striatal injection of 6-hydroxydopamine (6-OHDA). Adult male Wistar rats were divided into four groups: saline (SAL), sedentary (SED), exercised for 30 days before and 30 days after the induction of PD (EXB+EXA), and exercised for 30 days after the induction of PD (EX30A). These groups were further divided into two subgroups each, where half of the rats received K252a (K; a BDNF receptor blocker). To analyze their behavior, the rats were placed in an open field. The animals were placed on a treadmill 3 days/week at the speed of 10m/min during 40min. One month after 6-OHDA injections, the brains were collected for immunohistochemistry and immunoblotting assays, where we measured tyrosine hydroxylase (TH) in the substantia nigra pars compacta (SNc) and the striatum (CPu). BDNF was analyzed by immunoblotting in the groups without K. Statistical analyses were performed using one-way

ANOVA with the Tukey post hoc test.
The exercised groups exhibited reduced damage to dopaminergic cells, in terms of a higher postlesion TH expression. When we added K, TH expression decreased substantially.
There was a decrease of TH immunostaining in the SNc of SED animals without K, when compared to the SAL group (41%, $p<0.01$). The decrease also occurred in the groups receiving 6-OHDA and K (SED - 68%, $p<0.001$; EXB+EXA - 73%, $p<0.001$; EXA - 42%, $p<0.01$). We observed decrease in the immunoblots in the same groups: SED (53%, $p<0.001$), SED-K (42%, $p<0.01$), EXB+EXA-K (38%, $p<0.05$), e EXA-K (47%, $p<0.05$). The CPu provided data similar to those found in the SNc in all cases.
BDNF decreased in the SNc in the SED group (54%, $p<0.05$), which was the group that presented the lowest TH expression. The open field test revealed that the animals whose TH levels decreased explored more actively the environment in the second exposure, suggesting a memory deficit. The trained animals that received K showed the worst results (EXA+EXD - 38%, $p<0.05$; EXD - 32%, $p<0.05$). SAL and SED groups did not change after K injection.
Our data reveal that physical exercise is capable of reducing the damage induced by 6-OHDA, and that BDNF receptors are involved in that effect. Supported by FAPESP, CAPES, NAPNA - USP and CNPq (Brazil).

Title: Neuroprotective effect of Naringenin in Rotenone induced model of Parkinson’s disease

Authors: *S. ANGELINE[1], K. ANAND[2], A. SARKAR[2], K. SINGH[2], K. SHAH[2], P. CHATTTERJEE[2], R. AMBASTA[2], P. KUMAR[2]
[1]Vellore Inst. of Technol. Univ., Vellore, India; [2]VIT Univ., Vellore, India

Abstract: Parkinson's disease (PD) is a multifactoral age related neurodegenerative disorder eliciting death of dopaminergic neurons in the substantia nigra. Investigations have been done using experimental models of PD to understand the pathogenesis of the disease, especially, those produced by inducing neurotoxins like rotenone. Rotenone is linked to the development of PD as it interferes with the electron transport system in mitochondria. It is a well-known inhibitor of mitochondrial complex I. An increasing large body of research on Parkinson's disease (PD) has been focused on understanding the mechanisms behind the potential neuro protection offered by bioflavonoids. Rotenone induced rodent model of PD was generated, which was found to have debilitating phenotype and neurodegeneration. This study was aimed at investigating whether the natural phenolic compound naringenin can be neuro protective in the rotenone induced model of PD. Naringenin being powerful antioxidants also possess neuro protective and anti-ageing properties. Rotenone induced neurodegeneration and loss in motor skills was observed in the rodent model of PD. The histopathological analysis and immunofluorescence study of proteins of interest revealed betterment after oral administration of naringenin to the rotenone induced PD models. The drug significantly attenuated neurodegeneration in different regions of the rotenone treated PD rat brain. A modest increase in neuronal survivability was also found. In conclusion, treatment with bioflavonoid naringenin conferred neuro protection against rotenone induced neurotoxicity in PD rat model.

Title: Serum alpha synuclein and anti-alpha synuclein antibodies in healthy subjects and individuals with Parkinson's disease, atypical parkinsonism, or rapid eye movement sleep behavior disorder

Authors: *D. A. LOEFFLER[1], L. SMITH[1], M. COFFEY[1], A. KLAVER[1], M. SCHIESS[2]
[1]William Beaumont Hosp., ROYAL OAK, MI; [2]Univ. of Texas Med. Sch., Houston, TX

Abstract: α-synuclein is thought to play a prominent role in the pathogenesis of Parkinson's disease (PD) because it is the major protein in Lewy bodies, and because gene mutations and deletions increasing its expression and aggregation are associated with early-onset, autosomal dominant PD. There are conflicting reports as to the status of serum and plasma α-synuclein and anti-α-synuclein antibodies in PD, and the association between the levels of these proteins is unknown. The objectives of this study were therefore (1) to compare, by ELISA measurement, the concentrations of serum α-synuclein and anti-α-synuclein antibodies between subjects with PD (both idiopathic PD [n = 14] and atypical parkinsonism [n = 11]), rapid eye movement sleep behavior disorder (RBD; n = 10), and healthy controls (n = 9), and (2) to determine the strength and direction of association between serum α-synuclein and anti-α-synuclein antibody levels. Results: Mean concentrations for specific anti-α-synuclein antibodies (i.e., after subtraction of nonspecific binding of serum to BSA-coated wells) ranged from 0.97 to 1.46 μg/ml, and mean α-synuclein concentrations ranged from 6.92 - 10.51 ng/ml. Analysis on log-transformed data found no significant differences between groups for either concentration. Mean nonspecific binding of serum samples ranged from 28% to 41% of total binding to α-synuclein. No relationship was evident between serum anti-α-synuclein antibody or α-synuclein levels and subject age among all subjects; however, in subjects with idiopathic PD or atypical parkinsonism, specific antibody concentrations above 1.5 μg/ml were associated with shorter disease duration. Power analysis indicated that a two-sided t test on log - transformed data at the .05 level with 87 samples per group achieves 80% probability to detect a 50% increase in mean anti-α-synuclein antibody levels; similarly, 283 samples per group achieves 80% power to detect a 25% increase. Conclusions: This study found no evidence for differences in serum levels of anti-α-synuclein antibodies or α-synuclein between subjects with idiopathic or atypical PD, RBD, and healthy controls. Measurements of these proteins in peripheral blood are therefore not likely to be useful as biomarkers for early diagnosis of PD. The functional significance of anti-α-synuclein antibodies in normal subjects and individuals with PD requires further clarification. Title: Neuroprotective role of estradiol in MPTP-induced myenteric neuron degeneration

Authors: *M. COTE[1], M. BOURQUE[1], M. MORISSETTE[1], T. DI PAOLO[1,2], D. SOULET[1,3]
[1]CHUQ Res. Ctr. (CHUL), Quebec, QC, Canada; [2]Fac. of Pharm., [3]Fac. of Medecine, Dept. of Psychiatry and Neurosciences, Laval Univ., Quebec, QC, Canada

Abstract: Introduction: Patients suffering from Parkinson's disease (PD) frequently display non-motor symptoms like delayed gastric emptying, constipations and defecatory dysfunctions. These gastrointestinal dysfunctions are associated with the degeneration of dopaminergic (DA) neurons in the myenteric nervous system. Importantly, the immune system plays a critical role in the MPTP-induced degeneration of DA neurons in the myenteric plexus (MP) in mice. Of great interest, the hormone estradiol (E2) has shown immunomodulating properties in cell culture and is also well known to be neuroprotective in the central nervous system in animal models of PD. Since estrogen receptors (ERs) activation is associated with an increase of thrombosis, stroke and breast cancer risk, we decided to investigate the role of the new G-Protein coupled estrogen receptor-1 (GPER1) in the effect of E2 on MPTP toxicity.
Objectives: We aim to study the therapeutic potential of E2 and the activation of GPER1 in the MP of a PD mouse model.
Methods: Various treatments were performed in male mice with MPTP combined with E2, the GPER1 agonist G1 as well as its antagonist G15. MPs from distal ileum were microdissected and then processed for immunohistochemistry. Macrophage density and neuronal survival were assessed by stereology.
Results/Discussion: Treatment with MPTP induced 80% loss in tyrosine hydroxylase (TH)-positive neurons in the MP as well as a significant loss in TH-positive fiber density. This degeneration was accompanied with a 50% significant increase in macrophage density within the MP, suggesting that a strong immune response takes place locally. MPTP-treated mice receiving E2, G1 or E2+G15 showed no loss of TH neurons in the MP, while the G1+G15 treatment was inefficient to decrease the MPTP-induced DA neuronal death. In presence of E2 or G1, the immune response was also abolished. Altogether, these results suggest that the estrogen receptors alpha and beta as well as GPER1 are involved in the protection of DA neurons in the MP, and

could be potential therapeutic targets in gastrointestinal dysfunctions in PD.

Title: Quercetin and sesamin protect dopaminergic cells from MPP^+-induced neuroinflammation in a microglial-neuronal co-culture system.

Authors: J. RENAUD, J. BOURNIVAL, M. PLOUFFE, A.-M. AREL-DUBEAU, *M. MARTINOLI
Lab. Cell Neurobiol, Univ. Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: Growing evidence suggests that a majority of cases of Parkinson's disease (PD) are associated with microglia activation with resultant elevation of various inflammatory mediators and neuroinflammation. Cytokines have been proposed as candidates that mediate the apoptotic cell death of dopaminergic neurons implicated in PD. In this study, we investigated the effect of two natural molecules, quercetin and sesamin, on neuroinflammation induced by the parkinsonian toxin 1-methyl-4-phenylpyridinium (MPP^+) in a glial-neuronal co-culture system. Firstly, we established that quercetin or sesamin defend microglial cells from the MPP^+-induced increase of mRNA or protein levels of three proinflammatory cytokines (IL-6, IL-1alpha and TNFalpha) as revealed by RT-qPCR and ELISA assay, respectively. Quercetin or sesamin also decrease MPP^+-induced oxidative stress in microglial cells by reducing iNOS protein expression as well as mitochondrial superoxide radicals. We then measured neuronal cell death and apoptosis after MPP^+ activation of microglia, in a microglial-neuronal co-culture system. Our results demonstrated that quercetin or sesamin could rescue neuronal PC12 cells from apoptotic death induced by MPP^+ activation of microglial cells.
Altogether our results demonstrate that the phytoestrogen quercetin and the lignan sesamin diminishes MPP^+-induced microglial activation and suggest that these molecules may be regarded as potent natural anti-inflammatory compounds.

Title: α7 nicotinic acetylcholine receptor-mediated neuroprotection against dopaminergic neuron loss in an MPTP mouse model via inhibition of astrocyte activation

Authors: *H. JUN[1], Y. LIU[2], J. WU[3]
[1]Dept. of Orthopedics, The First Affiliated Hosp. of Nanjing Med. Univ., Jiangsu, China; [2]Dept. of Infectious Dis., the First Affiliated Hosp. of Nanjing Med. Univ., Nanjing, China; [3]Lab. of Neurophysiology, Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Background: Although evidence suggests that the prevalence of Parkinson's disease (PD) is lower in smokers compared to nonsmokers, the mechanisms of nicotine-induced neuroprotection remain unclear. α7 nicotinic acetylcholine receptor (α7-nAChR) stimulation appears to be a critical mechanism underlying the anti-inflammatory potential of cholinergic agonists in immune cells, including astrocytes. The inhibition of astrocyte activation has been proposed as a novel strategy for the treatment of neurodegenerative disorders such as PD. The objective of the present study was to determine whether nicotine-induced neuroprotection in an 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) mouse model occurs via α7-nAChR-mediated inhibition of astrocytes.
Methods: Both in vivo (MPTP) and in vitro (1-methyl-4-phenylpyridinium ion, MPP^+; lipopolysaccharide, LPS) models of PD were used to investigate the role(s) and the possible mechanism(s) whereby α7-nAChRs protect against dopaminergic neuron loss. Multiple experimental approaches, including behavioral tests, immunochemistry and stereology experiments, astrocyte cell cultures, reverse transcription-polymerase chain reaction, laser scanning confocal microscopy, TNF-α assays and Western blot, were employed to elucidate the mechanisms of α7-nAChR-mediated neuroprotection.
Results: Systemic administration of nicotine alleviated MPTP-induced behavioral symptoms, improved motor coordination, protected against dopaminergic neuron loss and the activation of astrocytes and microglia in the substantia nigra. The protective effects of nicotine were abolished by administration of the α7-nAChR-selective antagonist methyllycaconitine (MLA). In mouse primary cultured astrocytes, pretreatment with nicotine suppressed MPP^+- or LPS-induced astrocyte activation evidenced by both decreased production of TNF-α and inhibition of Erk1/2 and p38 activation in astrocytes, and these effects also were reversed by MLA.
Conclusion: Taken together, our results suggest that α7-nAChR-mediated inhibition of astrocyte activation is an important mechanism underlying the protective effects of nicotine.

Title: Induction of GDNF and neurotrophins by rasagiline and selegiline

Authors: *M. NAOI[1,2], K. INABA-HASEGAWA[3], M. SHAMOTO-NAGAI[4], W. MARUYAMA[4]
[1]Dept Neurosci, Gifu Internatl Inst. of Biotechnol, Gifu, Japan; [2]Dept. Hlth. Nutr., [3]Dept. Hlth. Nutr, Aichi Gakuin Univ., NIssin, Aichi, Japan; [4]Cognitive Brain Sci., Nat'L Ctr. Geriatric. Gerontol., Obu, Aichi, Japan

Abstract: Rasagiline and selegiline, inhibitors of type B monoamine oxidase (MAO-B), protect neuronal cells in animal and cellular models of neurodegenerative disorders. Molecular mechanism behind their neuroprotective action has been clarified to be the regulation of mitochondrial death signal pathway and the induction of pro-protective anti-apoptotic Bcl-2 and neurotrophic factors (NTFs). Type A MAO (MAO-A) was found to mediate the induction of Bcl-2 by these MAO-B inhibitors in MAO-A-expressing neuroblastoma SH-SY5Y cells. Rasagiline and selegiline increased the mRNA and protein levels of glial cell line-derived neurotrophic factor (GDNF) and neurotrophins [brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), neurotrophin 3 (NT-3)] in SH-SY5Y cells. Rasagiline increased GDNF more markedly than neurotrophins, and vice versa selegiline increased neurotrophins. The distinct induction of GDNF and neurotrophins by MAO inhibitors was also confirmed in non-human primates. Rasagiline was systematically administered in Japanese monkeys (n=4) for 4 weeks by daily subcutaneous injection, and the cerebrospinal fluid (CSF) was taken once a week. The NTF levels were quantified by the EIA assay. Rasagiline at 0.25 mg/day increased GDNF significantly, followed by BDNF, NGF and NT-3. On the contrary, selegiline increased BDNF in the CSF from parkinsonian patients treated with selegiline. The role of MAO-A and MAO-B in the induction of neurotrophins was investigated in wild SH-SY5Y cells and MAO-B-expressing glioblastoma U118MG cells. The effects of these MAO-B inhibitors on mRNA levels of neurotrophins were measured by use of real-time RT-PCR method. Rasagiline increased BDNF mRNA in wild SH-SY5Y cells, which was suppressed by treatment with siRNA against MAO-A, whereas selegiline increased BDNF mRNA in wild and siRNA treated cells. Selegiline and rasagiline induced BDNF mRNA in U118MG cells, and selegiline was more potent than rasagiline. These results suggest that NTF gene induction of rasagiline may depend on MAO-A, whereas selegiline may not in SH-SY5Y cells. In U118MG cells, these MAO-B inhibitors induce prosurvival NTFs through different signal pathway. The distinct signal pathway activated by rasagiline and selegiline may account for the preferential induction of GDNF and neurotrophins in animal and human experiments. The molecular mechanisms of the signal pathways should be further investigated to clarify the selective induction of these two NTF classes by rasagiline and selegiline.

Title: Intranasal GDNF for Parkinson's disease: Next steps in preclinical development

Authors: G. C. NEWSOME[1], L. WACHTMAN[2], M. M. MIGLIORE[4], A. ALY[5], N. SILVA[3], S. WESTMORELAND[3], J. ROWLETT[1], *B. L. WASZCZAK[6]
[1]Div. of Neurosciences, New England Primate Res. Ctr., [2]Div. of Vet. Resources, New England Primate Res. Ctr., [3]Div. of Comparative Pathology, New England Primate Res. Ctr., Harvard Med. Sch., Southborough, MA; [4]Pharmaceut. Sci., Massachusetts Col. of Pharm. and Hlth. Sci., Boston, MA; [5]Dept Pharmaceut Sci., Northeastern Univ., Boston, MA; [6]Dept Pharmaceut Sci., Northeastern Univ., BOSTON, MA

Abstract: We have previously shown that glial cell line-derived neurotrophic factor (GDNF) given by the nasal route of administration provides significant protection of substantia nigra (SN) dopamine neurons in the rat 6-hydroxydopamine (6-OHDA) model of Parkinson’s disease (PD) (Migliore et al., Soc. Neurosci. Abstr. #247.21, 2008 and #828.21, 2009). The next step in preclinical development is to evaluate the neuroprotective efficacy of intranasal GDNF in a primate model of PD. We have chosen the MPTP-lesioned marmoset model and selected an MPTP dose regimen which produces a partial lesion of the SN dopamine neurons, i.e. 2 mg/kg s.c. on day 1 and 1 mg/kg s.c. on days 2 and 3. We established in a pilot study that this regimen causes an approximately 50% loss of SN dopamine neurons and 65% decrease in tyrosine hydroxylase (TH) immunostaining density in the SN relative to that of unlesioned controls. To test the neuroprotective efficacy of intranasal GDNF, marmosets were anesthetized with ketamine and placed in a supine position with their noses upright. Doses were administered intranasally in five 10 µl aliquots at 5 min intervals alternating sides using a BD Accuspray device. GDNF (100 µg in 50 µl phosphate-buffered saline; n=9) or an equivalent volume of

saline (n=9) was given intranasally on 5 consecutive days. The first intranasal dose was given 1 day prior to the start of MPTP administration, and subsequent doses were given 1 hr prior to each of the 3 daily doses of MPTP, and 1 day after the last dose of MPTP. The animals were allowed to recover for 2 months prior to sacrifice. Lesion severity was assessed using both behavioral and neurochemical measures. Behavioral tests, including locomotor activity monitoring and performance on an object retrieval task, were performed for 2 to 8 wks prior to MPTP, respectively, and for the 2 months after MPTP. Motor disability scoring was performed biweekly after MPTP using a rating system devised for marmosets by Jenner and co-workers (Iravani et al, Eur. J. Neurosci. 21: 841, 2005). Neurochemical evidence of lesion severity was assessed by tyrosine hydroxylase (TH) immunohistochemistry (IH). Dopamine cell counts in the SN, and TH immunostaining densities in the SN and striatum of each animal, were used as measures of relative neuroprotection in the GDNF-treated animals.
The study concludes in September 2012. Results will be presented.

Title: Unsubstituted Phenothiazine is protective in the rotenone model of Parkinson’s disease

Authors: *V. TAPIAS[1], P. G. MASTROBERARDINO[2], X. HU[1], J. NELSON[1], T. SEW[1], J. T. GREENAMYRE[1,3]
[1]Neurol., Pittsburgh Inst. for Neurodegenerative Diseases. Univ. of Pittsburgh, Pittsburgh, PA; [2]Genet., Erasmus Med. Ctr., Rotterdam, Netherlands; [3]VA Healthcare Syst., Pittsburgh, PA

Abstract: Selective degeneration of dopaminergic (DA) neurons in the substantia nigra underlies the cardinal motor impairments of Parkinson’s disease (PD). Although the molecular mechanisms of pathogenesis remain unknown, there is substantial evidence that mitochondrial dysfunction and oxidative stress play key roles in the pathogenesis of PD. Inhibition of complex I enhances reactive oxygen species (ROS) formation; then, a feed-forward cycle ensues in which

local ROS production can damage complex I, increasing ROS production and leading to deleterious oxidation of lipids, proteins, and nucleic acids. Oxidative stress and mitochondrial dysfunction are early events in DA cell death evoked by rotenone, a pesticide implicated in human PD that crosses biological membranes. Rotenone had a detrimental effect, reducing the number of DA neurons and leading to shrinkage of neuronal processes as well as causing oxidative stress, both in *in vitro* cell systems and in animals. The aim of the current study was to evaluate the neuroprotective potential of several antioxidant drugs (which remain under-explored in the PD field) in the rotenone model *in vitro* and *in vivo*. Our *in vitro* drug screening revealed a neuroprotective role of various dosages of different drugs in primary ventral midbrain cultures, with a significant preservation of the number of DA neurons, neurite outgrowth, and protein thiol oxidation. Among the candidates, phenothiazine (PTZ) - an aromatic imine - was selected for the subsequent *in vivo* study for diverse reasons: PTZ exerts significant effects at nanomolar concentration, an EC_{50} value 100-10,000-fold lower than most other antioxidants, and may penetrate the BBB more effectively. Furthermore, PTZ has been shown to lack any significant DA receptor binding activity. Our data showed that post-treatment with PTZ (20 mg/kg/day BID) robustly protected against rotenone-induced nigrostriatal lesion in rats.

Title: Nicotine increases lifespan and rescues motor and olfactory deficits in parkin heterozygote loss-of-function *Drosophila* melanogaster

Authors: R. P. CHAMBERS, G. B. CALL, *T. JONES, L. M. BUHLMAN
Midwestern Univ., GLENDALE, AZ

Abstract: Parkinson’s disease (PD) is the most common neuromotor degenerative disease, affecting around 13 out of 100,000 people in the US, can exist in either sporadic or familial forms (Van Den Eeden *et al*., 2003). *Drosophila melanogaster* is a particularly attractive model for familial PD, as park25/park25 mutants exhibit many of the pathologies found in PD patients, including mitochondrial pathology, motor deficits and decreased lifespan. Progressive motor

deficits found in park25/park25 *D. melanogaster* are thought to result from mitochondrial pathology that causes indirect flight muscle degeneration (Greene *et al*., 2003). We have found that the heterozygote parkin loss-of-function *D. melanogaster* (park+/park25) have decreased lifespan, motor function and olfaction when compared with the park+/park+ (w1118). Epidemiological studies suggest that tobacco smokers are dose-dependently less likely to develop PD (Hernan *et al*., 2001; Grandinetti *et a*l., 1994; Rajput *et al*., 1987); subsequent *in vitro* and *in vivo* studies show that nicotine is protective in models of sporadic PD (reviewed in Quik *et al*., 2009). Lack effective PD therapeutic treatment could be due to the fact that extensive neurodegeneration has occurred by the time motor deficiencies appear and therapy is implemented. Evidence suggests that earlier therapeutic intervention could be more effective in halting or slowing disease progression (Jeyarasasingam *et al*., 2002) and prolonging patient quality of life. Olfactory deficits are one of the initial symptoms of PD, and we have determined that park+/ park25 also have olfactory deficits that precede motor deficits. Literature addressing the potential protection by nicotine in parkin loss-of-function models spans limited concentrations and selected time points in the organism's lifespan. Park+/ park25 were exposed to a range of nicotine concentrations from eclosion until behavioral assays were performed on days 5, 10 15 and 20. Our data show that at several concentrations and days of administration, nicotine can protect against the various deficits in this model of familial PD. Patients with inherited forms of PD can be easily identified via genetic testing. Our results suggest that early nicotinic therapeutic intervention in parkin-loss-of-function PD warrants further investigation.

Title: Δ9-Tetrahydrocannabinol and pioglitazone are protective in a cell culture model of Parkinson's disease through divergent PPARγ dependent mechanisms

Authors: *M.-L. ZEISSLER, C. O. HANEMANN, J. P. ZAJICEK, C. B. CARROLL
Dept. of Clin. Neurobio., PCMD, Univ. of Plymouth, Plymouth, United Kingdom

Abstract: Introduction: Cannabinoids such as Δ9-tetrahydrocannabinol (Δ9-THC) are neuroprotective in animal and cell culture models of Parkinson's disease (PD). In a PD cell culture model we recently demonstrated that Δ9-THC is neuroprotective through activation of

the nuclear receptor peroxisomal proliferator-activated receptor γ (PPARγ) and activation by specific agonists rosiglitazone and pioglitazone, has been found neuroprotective by others. Here we investigate downstream mechanisms of PPARγ receptor activation by Δ9-THC and pioglitazone.
Methods: SH-SY5Y neuroblastoma cells were differentiated with retinoic acid and exposed to the mitochondrial complex 1 inhibitor 1-methyl-4-phenylpyridine (MPP+) a neurotoxin known to induce a parkinsonian phenotype in man. Δ9-THC and pioglitazone were co-administered with the minimum concentration of the specific PPARγ antagonist T0070907 able to block the protective effect of each compound respectively for 48 hours. The production of reactive oxygen species was then measured and proteins were extracted for Western blotting.
Results: Although others have shown enhanced expression of the nuclear factor of kappa light polypeptide gene enhancer in B cells inhibitor alpha (IκBα) to be involved in PPARγ mediated neuroprotection against MPP+ we found that the expression of this protein was not significantly changed by Δ9-THC or pioglitazone. However, Δ9-THC resulted in significant inhibition of MPP+ induced oxidative stress which could be completely reversed with the PPARγ antagonist T0070907 whereas pioglitazone induced reduction in oxidative stress did not seem to be PPARγ dependent. Expression of the anti-oxidant enzymes catalase and superoxide dismutase 1 (SOD1) which are both known to have a PPARγ response element (PPRE) within their promoter region, remained unchanged by both pioglitazone and Δ9-THC. However, both pioglitazone and Δ9-THC were able to restore MPP+ induced downregulation of peroxisome proliferator-activated receptor-γ co-activator 1α (PGC1-α), a protein involved in oxidative stress response and mitochondrial biogenesis, to the level of untreated control. This effect was inhibited by T0070907 in the case of Δ9-THC but not pioglitazone.
Conclusions: Even though Δ9-THC and pioglitazone are both protective against MPP+ in a PPARγ dependent manner they appear to activate different downstream mechanisms.

Title: Protective effects of PACAP against salsolinol-induced toxicity in SH-SY5Y cells: Implications for Parkinson's disease

Authors: *D. O. BROWN[1], D. REGLODI[2], Y. TIZABI[1]
[1]Howard Univ. Col. of Medicine, Dept. of Pharmacol., Washington, DC; [2]Dept. of Anat., PTE-MTA Momentum PACAP Res. Group, Univ. of Pecs, Pecs, Hungary

Abstract: Pituitary adenylate cyclase-activating polypeptide (PACAP) is an endogenous neuropeptide with various cytoprotective functions including neuroprotection. Exogenous administration of PACAP has been shown to reduce damage induced by ischemia, trauma or toxic substances. Moreover, mice deficient in PACAP are more vulnerable to damaging insults. In this study we sought to determine whether PACAP may also be protective against salsolinol-induced toxicity in SH-SY5Y cells. Salsolinol (SALS) is an endogenous dopamine metabolite with selective toxicity to nigral dopaminergic neurons, which are directly implicated in Parkinson's disease (PD). SH-SY5Y cells, derived from human neuroblastoma cells express high level of dopaminergic activity and are used extensively as a model to study these neurons. Exposure of SH-SY5Y cells to 400 uM SALS for 24 h resulted in approximately 40% toxicity as determined by MTT assay. Pretreatment with PACAP (1-38) dose-dependently attenuated SALS-induced toxicity with maximal protection (approx. 62%) by 200 nM PACAP. The effects of PACAP in turn were dose-dependently blocked by PACAP antagonist (PACAP 6-38) with full antagonism at 2 uM. PACAP (6-38) is a strong blocker of PAC1 receptor. Neither PACAP (1-38) nor PACAP antagonist (6-38) had any effect of their own on cellular viability. These results suggest protective effects of PACAP in a cellular model of PD. Moreover, the effects of PACAP appear to be mediated through PAC1 receptor. Hence, PACAP or PAC1 agonists could be of therapeutic benefit in PD.

Abstract: We previously reported the *in vivo* discovery of P7C3, an aminopropyl carbazole endowed with proneurogenic and neuroprotective properties in newborn neural precursor cells in the subgranular zone of the dentate gyrus. We now show that P7C3 additionally displays neuroprotective efficacy in mature neurons as well. P7C3 blocks MPTP-mediated cell death of dopaminergic neurons in the substantia nigra of adult mice, as well as in dopaminergic neurons of *Ceanorhabditis elegans*. In both *in vivo* paradigms of toxicity, the P7C3 analog P7C3A20 blocks cell death with greater potency and efficacy than P7C3. This parallels the relative potency and efficacy of these molecules in blocking apoptosis of newborn neural precursor cells of the dentate gyrus. The chemical scaffold represented by P7C3 and P7C3A20 may serve as a basis for developing new pharmacologic agents for treating patients with Parkinson's disease.

Title: Characterization of a novel peroxidase (PXDNL) and its interaction with the molecular chaperone HSP90.

Authors: *E. K. HOFFMAN[1,2], J. T. GREENAMYRE[2]
[1]Univ. Pittsburgh, PITTSBURGH, PA; [2]Neurol., Univ. Pittsburgh, Pittsburgh, PA

Abstract: Parkinson's disease (PD) is the second most common age-related neurodegenerative disease with pathological characteristics including reduced activity of mitochondrial complex I and loss of dopaminergic neurons in the substantia nigra. Despite the fact that the etiology of PD

has been the focus of extensive investigation, the genetic and biochemical pathways leading to the onset and progression of PD remain poorly understood. The environmental toxin rotenone may increase the risk of PD in humans, and has been used to model the disease in rodents. It is believed that rotenone's toxicity is due to inhibition of mitochondrial complex I, leading to increased oxidative stress and reduced ATP production. Recent evidence from our laboratory has demonstrated that overexpression of a heme peroxidase, PXDNL (Peroxidasin homolog Drosophila-like), is associated with increased resistance to rotenone and hydrogen peroxide toxicity. In the present study we characterize the interaction of PXDNL protein with the molecular chaperone HSP90 in the human neuroblastoma cell line SH-SY5Y. Co-immunoprecipitation studies identified HSP90 as a binding protein interacting with PXDNL. Treatment of cells with rotenone resulted in transcriptional up-regulation of both PXDNL and HSP90. This change in gene expression may represent a novel neuroprotective mechanism initiated in response to toxic stress. We hypothesize that the interaction of PXDNL with HSP90 is a uniquely attractive target for therapeutic manipulation in PD.

Title: Cooperation between prenatal MPTP and postnatal SAM in the reduction of striatal dopamine, DOPAC and 3-MT in C57BL mice.

Authors: *G. MUTHIAN, M. SMITH, V. MACKAY, B. GRIFFIN, C. CHARLTON
Neurosci. & Pharmacol., Meharry Med. Col., NASHVILLE, TN

Abstract: Parkinson's disease (PD) is marked by the loss of dopamine (DA) neurons in the substantia nigra and DA depletion in the striatum. The cause is unknown. Our lab demonstrated that S-adenosy-L-methionine (SAM), the product of ATP and methionine, caused PD-like changes in rodents. SAM is the biological methyl donor, is ubiquitous and its activities are increased in aging. SAM avidly reacts with and destroys DA and L-dopa, therefore, it may contribute to the reduction of DA seen in PD. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine

(MPTP) is also a toxin to DA neurons, so MPTP and SAM were used to test the hypothesis that a **sensitization stage and a precipitating stage** underlie idiopathic PD. To induce the **sensitization stage**, pregnant C57BL/6J mice were treated with MPTP (10mg/kg/dy) during gestation days 8-12 to target the emerging fetal nigrostriatal DA neurons. For the **precipitating stage**, the 3-months old offspring were administered dosage of SAM into the lateral ventricle, to simulate an age-related change; since methylation is increased during aging and SAM depletes DA and methylates and down-regulates DA receptors. Both the prenatal MPTP (MPTP+PBS) and postnatal SAM (PBS+SAM) treatments reduced DA and its metabolites. As compared to the control (PBS-PBS) offspring prenatal MPTP (MPTP+PBS) reduced DA by 32.1%. In the PBS control icv SAM of 0.125µmol, 0.25µmol and 0.5µmol reduced DA by 46.7, 67.2 and 75.1%. In the prenatal MPTP offspring the same dosage of SAM reduced DA by 72.8, 76.9 and 92.0%. Similar changes were noted for DOPAC and 3-MT. The study showed that prenatal exposure to the toxin, MPTP, caused sub-threshold harm to the striatal dopaminergic system and that a naturally occurring metabolite, SAM, that is increased during aging had an additive effect in reducing DA to the threshold at which PD-symptoms are seen, thus SAM may be considered a precipitating factor. SAM is produced by all cells, controls multiple reactions and may be one of the metabolites that allow aging to be a major risk factor for PD and for other degenerative disorders.

Title: Rationally designed PKD1 activator protects against neurodegeneration in pre-clinical models of Parkinson’s disease

Authors: *A. G. KANTHASAMY, A. ASAITHAMBI, A. GHOSH, M. AY, H. JIN, M. NEAL, K. MULLIN, V. ANANTHARAM, A. KANTHASAMY

Abstract: Oxidative stress has been implicated as a major pathological mechanism in the degenerative processes underlying Parkinson's disease (PD). The key signal transduction and regulatory networks involved during the degenerative process in PD are currently being explored for identification of novel neuroprotective strategies. We recently discovered that the activation of Protein Kinase D1 (PKD1) acts as a novel compensatory mechanism in PD models, and positive modulation of PKD1 can offer neuroprotection against oxidative damage of dopaminergic neurons (Asaithambi et al., 2011. Mol Neurodegener. 6:43). Consistent with these findings, herein we show that positive modulation of PKD1 activity by using constitutively active PKD1 or pharmacological PKD1 activator protected against MPP+ and 6-OHDA-induced toxicity in cell culture PD models, whereas pharmacological inhibition of PKD1 activity with the small molecule inhibitor kbNB 142-70 exacerbated the neurotoxicity. To extend our translational strategy, we rationally designed and synthesized PKD1 activator peptides and further characterized their neuroprotective role in pre-clinical models of PD. Following the extensive screening, the peptide AK-P4 was identified to activate PKD1 specifically, and protected against MPP+ and 6-OHDA-induced neurotoxicity cell culture models of PD. Importantly, intravenous administration of AK-P4 tagged with TAT sequence (AK-P4T) significantly activated PKD1 in mice. The neuroprotective effects of AK-P4T were tested in the MPTP-induced PD model. Co-treatment with AK-P4T significantly protected against MPTP-induced behavioral deficits, neurotransmitter depletion and histological cell loss. Collectively, our results demonstrate that rationally designed PKD1 activator peptide AK-P4T protected against neurodegeneration in the pre-clinical models of PD. These results suggest that positive modulation of PKD1 using AK-P4T peptide shows promise as a potential therapeutic agent against PD.

Title: Aldehyde dehydrogenase 1 determines the regional selectivity of nigral neuron loss in Parkinson disease

Authors: *G. LIU
NIA, NIH, BETHESDA, MD

Abstract: While a preferential degeneration of nigral dopaminergic (DA) neurons is well recognized in Parkinson disease (PD), less is known about the regional selectivity of DA neuron loss within the substantia nigra pas compacta (SNpc). This differential susceptibility of nigral DA neurons in PD indicates the existence of diverse subpopulations of DA neurons in the SNpc, which may possess the molecular clues critical for understanding the cause of nigral neurodegeneration in this disease. Here we show that aldehyde dehydrogenase 1 (ALDH1A1), an enzyme involved in oxidation of dopamine-derived aldehyde intermediates, contributes to the regionally selective loss of nigral DA neurons in PD. ALDH1A1 is selectively expressed by DA neurons located in the ventrolateral (VL) tier of SNpc in the rodent brain, which may divide the nigral DA neurons into two subpopulations along the dorsomedial (DM) to VL axis. Interestingly, we found in a line of PD-related mutant α-synuclein transgenic mice, the progressive loss of DA neurons mainly occurred in the DM tier of SNpc that lacks the expression of ALDH1A1. Furthermore, genetic ablation of ALDH1A1 exacerbated the degeneration of nigral DA neurons in these mice, supporting a protective function of ALDH1A1 against α-synuclein-induced nigral DA neuron loss. Consistent with our findings in the mouse model, ALDH1A1 also displayed a conserved topographic distribution in the ventral tier of human SNpc. In particular, a similar preferential loss of ALDH1A1-lacking dorsal nigral neurons was evident in the SNpc of patients with sporadic PD. Therefore, our findings establish ALDH1A1 as a key molecular determinant of the regional vulnerability of nigral DA neurons in PD, suggesting that ALDH1A1 may protect against nigral DA neurodegeneration by preventing the cytotoxic accumulation of α-synuclein aggregates.

Abstract: Parkinson disease (PD) is a neurodegenerative disorder of unknown etiology characterized by the loss of dopaminergic neurons in the substantia nigra compacta (SNc), conventional therapy with L-Dopa produces adverse effects after the prolonged period of administration probably due to the generation of free radicals. Melatonin has endogenous antioxidant actions. Previously we concluded that the co-administration of some antioxidants like melatonin with L-Dopa, helps to reverse some alterations induced by L-Dopa treatment. Researches show that adult rat SNc progenitor cells have the capability of differentiation into neurons under adequate environmental stimuli. Thus, we proved the L-DOPA effect, separately and with the co-administration L-dopa/Melatonin number neurogenesis in the SNc of rats lesioned with 6-OHDA. Our results show a greater number of TH/BrdU positive neurons in the L-Dopa/Melatonin treated group compared to 6-OHDA group and animals treated only with L-Dopa or Melatonin. We concluded that L-Dopa/Melatonin co-administration could promote the generation of new dopaminergic neurons in the SNc probably by reducing the oxidative environment

Title: Glyceryl-tris-3-hydroxybutyrate protects dopaminergic neurons in a MPTP model of Parkinson's Disease

Authors: *J. BLESA[1], V. JACKSON-LEWIS[1], N. BOAZ[2], S. HASHIM[3], S. PRZEDBORSKI[1]
[1]Columbia Univ., New York, NY; [2]Eastman Chem. Co., Kingsport, TN; [3]Dept. of Med., St. Luke-Roosvelt, New York, NY

Abstract: Parkinson's Disease (PD) is the second most neurodegenerative disease after Alzheimer Disease. It is a sporadic condition and several lines of evidence suggest that a defect in oxidative phosphorylation contributes to its pathology. Previously, we have shown that the administration of D-B-Hydroxybutyrate (DBHB) mitigates tyrosine hydroxylase positive (TH+) neuronal loss in the substantia nigra pars compacta of mice caused by mitochondrial poisons such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). DBHB is a ketone body produced by hepatocytes and astrocytes and is an alternative source of energy in the brain. We noted that this beneficial effect is mediated by the stimulation of ATP production in mitochondria. At this point, the long-term effects of the chronic use of DBHB are not known. One major limitation to the clinical use of DBHB resides with its extremely short half-life, hence, requiring its infusion via Alzet pumps to reach effective steady-state levels in the blood. Because of the short half-life of DBHB, an analogue of the DBHB, Glyceryl-tris-3-hydroxybutyrate (3GHB), was synthesized. This compound has a pharmacokinetic suitability for single-dose daily administration. We, therefore, have tested 3GHB to gauge the effectiveness of its "extended" neuroprotective action, both in *in vivo* and *in vitro* studies in comparison to DBHB. We show that 3GHB protects SNpc dopaminergic neurons against MPTP in a dose dependent manner and prevents the development of abnormalities in mice. Also, we have preliminary data suggesting that this protection may be via inhibition of histone deacetylase activity (HDAC). This new analog may represent a promising and valuable therapeuthic strategy for a range of pathological conditions affecting the brain, such as Parkinson's Disease or Alzheimer's Disease.

Title: Cav1.3 LTCC selective inhibition by 1-(3-chlorophenethyl)-3-cyclopentylpyrimidine-2,4,6-trione in ameliorating PD motor deficits

Authors: *G. COOPER, JR[1], D. J. SURMEIER[2], R. B. SILVERMAN[3], J. N. GUZMAN[2], D. J. GALTIERI[2], S. KANG[3]
[1]Chem., Northwestern Univ. -- Dept. of Chem., Evanston, IL; [2]Physiol., Northwestern Univ., Chicago, IL; [3]Chem., Northwestern Univ., Evanston, IL

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disease, in which the primary motor deficits are the result of selective degeneration of mesencephalic dopaminergic neurons (DA) in the substantia nigra pars compacta (SNc). We have shown that SNc DA neuronal physiology engages a low-threshold, high-conductance, long-lasting voltage-dependent calcium channel with a Cav1.3 pore-forming subunit. Cav1.3 L-type calcium channels (LTCCs) are engaged throughout the pacemaking cycle of adult SNc DA neurons, allowing extraordinary amounts of calcium into SNc DA neurons -- manifested as phasic dendritic calcium oscillations. As a consequence of increased intracellular free calcium, mitochondrial oxidative phosphorylation in SNc DA neurons increases to enable ATP-dependent calcium buffering mechanisms. These active buffering mechanisms are metabolically expensive -- leading to increased reactive oxygen species production. Inhibiting Cav1.3 LTCCs non-selectively via 1,4-dihyropyridines (DHPs) attenuates these dendritic calcium oscillations, relieves mitochondrial oxidant stress, and is neuroprotective in PD animal models. DHPs are a class of FDA approved anti-arrhythmic and anti-hypertension small organic molecules, which have nanomolar affinities to all neuronal LTCCs. Thus, chronic treatment of DHPs for PD preventive purposes might have unintended physiological consequences. Using whole-cell voltage-clamp electrophysiology, we present the first Cav1.3 LTCC isoform selective small molecule 1-(3-chlorophenethyl)-3-cyclopentylpyrimidine-2,4,6-trione (PYT), which selectively inhibits Cav1.3 LTCCs in a voltage-dependent and reversible manner. In addition, using two-photon laser scanning microscopy (2PLSM), we show PYT attenuates dendritic calcium oscillations and reduces mitochondrial oxidant stress. In conclusion, PYT represents a novel pharmacological tool in calcium channel physiology and potential therapeutic measure in slowing the progression of SNc DA neuronal degeneration in PD.

Title: Expression of BDNF in reactive astrocytes provides neuroprotection to SH-SY5Y cells against 6-OHDA toxicity *in vitro*

Authors: *Y. TSANG[1], *Z. X. BIAN[2], K. YUNG[2]
[1]Dept. of Biology, Hong Kong Baptist Univ., Hong Kong, China; [2]Biol., Hong Kong Baptist Univ., Hong Kong, China

Abstract: Brain-derived neurotrophic factor (BDNF) has been shown to enhance the survival of dopaminergic neurons and to protect them against the neurotoxic effects of 6-hydroxydopamine (6-OHDA), a specific neurotoxin to dopaminergic neurons (Bove *et al*., 2005). Nestin is an embryonic protein and is a marker for neural stem cells. Nestin is not found in mature astrocytes. In our previous studies using rodent models of Parkinson's disease, a few nestin-immunoreactive reactive astrocytes were found to appear and express BDNF after the onset of Parkinson's disease (Chung *et al*., 2008). In order to investigate the neuroprotective roles of BDNF in reactive astrocytes, primary cell cultures of rat astrocytes were employed in the present study. By immunocytochemistry and Western blot analysis, a vast proportion of astrocytes in culture were found to be nestin-immunoreactive. In addition, most of these reactive astrocytes were found to express BDNF immunoreactivity. Reactive astrocytes were treated with BDNF (5, 50, 100, 200 ηg/ml). The levels of BDNF expression were found to be further enhanced and up-regulation of p-MEK and p-Erk1/2 in astrocytes were found by Western blot analysis. Moreover, when BDNF treated reactive astrocytes were co-cultured with neuroblastoma SH-SY5Y cells, activation of Akt and MAPK pathway were found by Western blot analysis. Cells in co-cultures were then treated with 6-OHDA (40μM), significant reductions of cell death of SH-SY5Y cells were found. The present results as a whole indicate that astrocytes *in vitro* display characterizations of reactive astrocytes and express high levels of BDNF. Administration of BDNF can stimulate further expression of BDNF in reactive astrocytes through activation of the MAPK pathway.

Title: Neuro-protective effect of oxytocin on rotenone-induced Parkinson's disease in rats

Authors: *O. ERBAS, F. OLTULU, D. TASKIRAN
Physiol., Ege Univ. Fac. of Med., Izmir, Turkey

Abstract: Aim: Our study was undertaken to investigate the neuroprotective effects (if any) of oxytocin (OT) on rotenone-induced Parkinson's disease (PD) in rats. OT is essentially associated with uterine contraction during parturition and milk ejection reflex. Although several studies have implicated the role of OT in other behavioral, and neuroprotective processes involving the anti-inflammatory, anti-oxidative and anti-apoptotic pathways, there is insufficient data with regard to the latter features of OT in neurodegenerative models such as Parkinson's disease (PD).
Material-Methods: Eighteen adult male Sprague-Dawley rats were stereotaxically injected with rotenone (an abundantly used pesticide and insecticide; 3 μg/ μl in DMSO) and vehicle (DMSO) into the left substantia nigra pars compacta and ventral tegmental area, and the expression of PD was verified by apomorphine-induced rotational test 10 days post-infusion. The valid PD rats were randomly divided into two groups: Group 1 (n= 6) and Group 2 (n=6) were administered saline (1 ml/kg/day, i.p.) and OT (160 μgr/kg/day, i.p.) through 20 days, respectively. The effects of OT treatment were evaluated by behavioral, immunohistochemical and electrophysiological analysis.
Results: Apomorphine-induced stereotypic rotations in PD rats were significantly inhibited by OT treatment ($p<0.05$). EEG analysis showed that OT treatment significantly reversed PD-induced changes ($p<0.0001$). In addition, immuno-histochemical data clearly demonstrated suppression of i-NOS, Bax, caspase-3, caspase-8, and elevation of Bcl-2 and tyrosine hydroxylase immune-expression in OT-treated rats.
Conclusion: Our findings suggest that OT may have neuroprotective effect on in vivo PD model. The underlying mechanisms might be involved with the anti-apoptotic effects and/or anti-inflammatory effects of OT. Next, we foresee enlightening the sites and mechanisms of action relevant to OT in this model.

Title: PAOPA, an allosteric modulator of dopamine D2 receptor, enhances the therapeutic effects of levodopa in the *C. elegans* model: Implications for adjunctive therapy for Parkinson's disease.

Authors: A. H. SIDDIQI[1], B. P. GUPTA[2], P. R. SELVAGANAPATHY[3], R. JOHNSON[4], *R. K. MISHRA[5]
[1]Psychiatry and Behavioral Neurosci., [2]Biol., [3]Mechanical Engin., McMaster Univ., Hamilton, ON, Canada; [4]Medicinal Chem., Univ. of Minnesota, Minneapolis, MN; [5]Psych & Behav Sci., McMaster Univ. Hsc-4N 78, Hamilton, ON, Canada

Abstract: Parkinson's disease (PD) is a complex neurodegenerative disorder characterized by the selective and progressive degeneration of dopaminergic neurons within the substantia nigra. Although medications such as amantadine, monoamine oxidase B inhibitors and catechol-O-methyl inhibitors are effective in treating the disease, with time, every patient requires Levodopa treatment. However, despite being considered the gold standard treatment of PD, chronic use of levodopa leads to dyskinesia and wearing off or on-off phenomena. Therefore, there is a need to investigate efficacious therapeutics that not only treat the symptoms of PD but also have limited debilitating side effects. The aim of the present study was to screen potential therapeutics for PD in model genetic organisms like Caenorhabditis elegans (C. elegans). Worms show degeneration of dopaminergic neurons and movement deficits suggestive of PD when exposed to neurotoxins such as 6-Hydroxydopamine (6-OHDA). Conventional behavioral assays can be very subjective and labor intensive because they involve manually counting the nematodes and observing their movement on a plate. Recently, a novel microfluidics-electrotaxis system has been developed that allows for the high throughput study of behavioral deficits in C. elegans. This assay relies on the feature of C. elegans sensory neurons to mediate attraction towards the cathode in a DC electric field. Previous results have revealed the effectiveness of this system in studying PD, as the neurotoxin 6-OHDA-treated worms were defective in electrotactic behavior, showing a reduced swimming speed. The results of the current study demonstrate that co-administration of the neuroprotective compound Levodopa and Carbidopa are protective against 6-OHDA toxicity, and this protection was further enhanced when administered with PAOPA ((3(R)-[(2(S)-pyrrolidinylcarbonyl) amino] -2-oxo-1- pyrrolidineacetamide)), the confirmationally constrained analog of Pro-Leu-glycinamide. PAOPA is a specific allosteric modulator for the dopamine D2 receptor, which potentiates the effects of dopamine in the system. PAOPA has been shown to cross the blood brain barrier and have very low toxicity. This provides support for a potential role of PAOPA as an adjunctive therapy for the treatment of PD and to reduce the necessary dose

of levodopa thus minimizing the risk of levodopa induced diskinesia. This work was supported by CHRP grant from CIHR-NSERC and NIH (USA).

Title: The C-terminal domain of tetanus toxin has neuroprotective and restorative effects that leads improvement of the motor behavior and decrease the striatal neurodegeneration of rats with 6-hydroxydopamine

Authors: *A. SÁNCHEZ GONZÁLEZ[1], L. MENDIETA[1], P. DE LA CRUZ[1], V. PALAFOX[1], M. HERRANDO[2], J. AGUILERA[2], J. GUEVARA[3], D. LIMÓN[1]
[1]Lab. De Neurofarmacología/Benemerita Univ. Autonoma De Puebla, Puebla, Mexico; [2]Inst. de Neurociènces, Departament de Bioquímica i de Biología Mol., Univ. Autònoma de Barcelona, Barcelona, Spain; [3]Dept. de Bioquímica, Facultad de Medicina, Univerdad Nacional Autónoma de México, México DF, Mexico

Abstract: The C-terminal domain of tetanus toxin (Hc-TeTx) is a peptide that lacks the toxicity of the whole neuromuscular toxin and has a neuroprotector activity against dopaminergic damage with MPP^+ in vitro and in vivo. The trophic effects of Hc-TeTx are related to its ability to active tyrosine kinase receptor’s pathways, which are crucial for survival process. The aim of our study was examined the neuroprotective and restorative effects in the nigrostriatal system by the intramuscular injection of the Hc-TeTx fragment in hemiparkinsonian rats. Animals were administered with vehicle (ISS) or Hc-TeTx (20 µg/kg) in the gastrocnemius muscle for three consecutive days pre- or post- the dopaminergic lesion with 6-hydroxydopamine (6-OHDA). Previous to the surgery the rats were administered ketamine/xylazine (55/5 mg/Kg i.p.) to underwent the intrastriatal injection of 6-OHDA (16 µg / 2µL) or vehicle (2µL of ascorbic acid at 0.01%) by stereotactic surgery. Therefore, we obtain groups with vehicle and groups with 6-OHDA, of which we obtain pre- or post-Hc-TeTx treatment groups. Animals with pre-Hc-TeTx

treatment were tested for rotational behavior with methamphetamine (5 mg/kg s.c.) after 2 weeks from lesion and the animals with post-Hc-TeTx treatment were tested for rotational behavior 8 days after surgery. For all groups, the motor asymmetry were tested every 7 days over a month in the cylinder test and then the neurodegenerative process in the nigrostriatal system was examined by the aminocupric-silver staining and tyrosine hydroxylase immunoreactivity (TH-IR). Our results showed that the pre-treatment with Hc-TeTx prevents the motor asymmetry by 6-OHDA during rotational behavior by methamphetamine (24 turns/h) and in the cylinder test (~70% of use of both forelimbs), in contrast with the 6-OHDA group (500 turns/h and ~22 %, respectively). In addition, the pre-Hc-TeTx hemiparkinsonian rats showed a major TH-IR in the striatum and SNpc respect to 6-OHDA group and we found minor argyrophilic-structures as a marker of neurodegeneration in the ipsilateral striatum of these animals after one month. The hemiparkinsonian rats with post-Hc-TeTx treatment showed a constant motor asymmetry (~60%) compared with its control 6-OHDA group (~30%). Moreover, the ipsilateral striatum of post-Hc-TeTx group has a lower number of argyrophilic-estructures and a major TH-IR in striatum and the SNpc compared to the 6-OHDA group. In summary, the intramuscular injection of Hc-TeTx has the ability to delay the progression of motor asymmetry, decrease the neurodegenerative process in striatum and prevent the progression of dopaminergic neurons death before and after 6-OHDA lesion.

Title: The neuroprotective efficacies of dichloroacetate with potent bioantioxidant polyphenols, resveratrol and curcumin, against neurotoxic-induced Parkinson's disease in neuroblastoma cells *in vitro*

Authors: *A. BETTICA, N. Y. YOUSAF, T. ZELEKE, M. GEBREMICHAEL
Manhattanville Col., Purchase, NY

Abstract: Accumulation of reactive oxygen species (ROS), due to increased oxidative stress, may lead to neuronal cell loss with strong associations to neurodegenerative disorders, such as Parkinson's disease (PD). Dichloroacetate (DCA), a small, readily available sodium salt, has

been shown in cancer cells to restore damaged mitochondrial function. Many polyphenolic compounds have been shown to be strong antioxidants and possible neuroprotective agents. In animal studies, resveratrol, an active constituent of red wine extracts, was shown to reduce beta-amyloid plaques by its possible copper-binding mechanisms. Curcumin, from the ginger family, acts as a scavenger and chelator, which also reduces plaques and can directly inhibit MPP+ toxicity in several neuronal cell lines. To determine the neuroprotective efficacies of DCA and potent bioantioxidants with relationship to the oxidative stress-induced *in vitro* PD model, pretreatments of neuroblastoma cells with these individual and combination agents against the neurotoxic insults, MPP+ and 6-OHDA, were undertaken. To formulate dose-response curves, the cells were pretreated in 96-well plates with each of the serially-diluted agents added for 24 hours before a potent dose of MPP+, a mitochondrial complex I inhibitor, or 6-OHDa, a potential ROS generator. For posttreatment studies, the cells were exposed to each insult first for 24 hours, followed by the antioxidants for 24 hours. Cotreatments with each agent and the neurotoxic insults were performed to elucidate possible preconditioning or gene activation versus actual mechanisms of action. Combination treatments were determined through
single concentration-dependent effective dosages. The MTT mitochondrial and Neutral Red lysosomal assay were used to assess cell viability/cell proliferation of triplicate data sets. All single treatment studies showed significant neuroprotection over a range of concentrations. DCA seemed to be the most effective in protecting the cells against MPP+ than against 6-OHDa. DCA lowered the effective dose for curcumin, however the pretreatment combination studies favored DCA with resveratrol over curcumin. Biphasic dose-response curves and poor availability of the polyphenols need to be carefully considered. If the polyphenols prove to be neuroprotective agents either singly or in combination, their bioavailability could be improved with attachment of phosphatidylcholine or linkage to a phytosome. But it is the multiple beneficial effects of these constituents, with little toxic side effects, that offers great potential for the prevention or treatment of Parkinson's disease and other neurodegenerative disorders.

Title: Antiapoptotic effects of 2,3-dichloro-1,4 naphthoquinone derivatives on salsolinol-induced toxicity in human shsy-5y cells.

Authors: S. T. WHITE[1], *R. L. COPELAND, Jr[2]
[1]Pharmacol., Howard Univ., Washington, DC; [2]Howard Univ. Col. Med., Washington, DC

Abstract: The cause and underlying mechanism of chronic cell death of the neural tissues in Parkinson's disease (PD) remains elusive. Salsolinol, (1-methyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline) is an endogenous catechol isoquinoline detected in the brain, the cerebrospinal fluid and the urine. Elevated levels of salsolinol (SAL) have been detected in patients with idiopathic PD, which have also been proposed as biological markers of PD as they may result from an altered metabolism of dopamine. Several studies indicated that SAL is toxic to dopaminergic neurons in vitro as well as in vivo. Previous studies have shown that 2,3-dichloro-1,4 naphthoquinone (2,3DCNQ) derivatives possess a wide variety of biological responses including antibacterial, antifungal, anti-inflammatory, antiviral and anticancer. However, these compounds are known to have biphasic effects and at low nM concentrations these compounds have neuroprotective activity. This study was designed to evaluate the neuroprotective effect of 2,3DCNQ derivatives against SAL-induced cytotoxicity in the human neuroblastoma cell line, SH-SY5Y, by inhibition of apoptosis. Exposure of SH-SY5Y cells to 0.2 and 0.5 mM SAL for 24 hours resulted in 40 to 70 % cell death respectively as determined by WST-8 cell proliferation assay. Cells pretreated for 60 minutes with 15 nM 2,3DCNQ resulted in attenuation of salsolinol-induced cytotoxicity. Data was further supported by cell flow cytometry analysis which showed the highest number of early plus late apoptotic cells in SAL treated group exposed for 24 h. The 2,3DCNQ pretreatment reduced the apoptotic cell death. Western Blot analysis showed increased Akt activation. In nM concentrations, 2,3DCNQ appears to be specific for the antiapoptotic pathway, particularly PI3/Akt. This study suggests that 2,3DCNQ protect SH-SY5Y cells from SAL-mediated cytotoxicity by suppressing apoptosis. Since PD is a slowly progressing neurodegenerative disease, associated with excitotoxicity and apoptosis, therapeutic strategies exhibiting anti-apoptotic potential could be developed as a possible target to treat PD.

Title: RAAV-mediated shrna knock-down of gd3 synthase (gd3s) reverses “executive” deficits in parkin null mice

Authors: *E. O. AKANO[1,2], M. P. MCDONALD[2,3], T. S. REX[4]
[1]Program in Neurosci., [2]Dept. of Neurol., [3]Anat. and Neurobio., [4]Dept. of Opthalmology, Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: The purpose of this study was to address two unmet needs in Parkinson’s disease therapeutics. The current therapies do not address the cognitive manifestations of the disease, and more importantly, they are not neuroprotective. The goal of the present project was to characterize the cognitive deficits in parkin null mice and to determine whether knocking down GD3 synthase (GD3S) would reverse these and other deficits exhibited by the knockouts. Inhibition of the gene (St8sia1) that codes for the ganglioside biosynthetic enzyme GD3S increases levels of GM1 ganglioside while inhibiting the expression of the pro-apoptotic GD3 ganglioside. GM1 has neuroprotective and noötropic properties, inhibits the fibrillization of α-synuclein in vitro, and partially protects nigrostriatal neurons in MPTP-treated mice. We trained knockouts and age-matched wild-type littermate controls on a 3-hole serial reaction time task commonly used to assess sustained attention, but modified to include indices of impulsive behavior. At baseline, using 1-s cue duration, there was no significant difference in accuracy (hits) across genotype, although reaction time and hopper latencies were slower in the parkin null mice compared to controls. On sessions with pseudo-randomized shorter cue durations (0.125-1.0 s), the parkin knockouts had significantly fewer hits and significantly slower reaction times than wild-type controls. During a probe session using variable inter-trial intervals, the parkin null mice had fewer hits, slower reaction time, and increased premature responses, indicating impaired attention and increased impulsivity. At the age of 13 months, the experimental subjects had intrastriatal injections of shRNA targeting GD3S or a scrambled control (scrRNA). Injection of GD3S.shRNA reversed the deficits in the reaction time task using variable cue durations. This study shows that parkin null mice can be used to study “executive” deficits characteristic of Parkinson’s disease and that knockdown of GD3S warrants further investigation as a potential therapeutic agent for Parkinson’s disease.

Title: Oxicam non-steroidal anti-inflammatory drugs ameliorate motor dysfunction and dopaminergic degeneration by maintaining Akt-signaling in a mouse Parkinson's disease model.

Authors: *Y. TASAKI[1], J. YAMAMOTO[1], T. OHKUBO[1], T. NODA[1], T. OMURA[1], T. ONO[1], N. KIMURA[1], M. SUNO[2,1], T. SAKAGUCHI[1], K. MATSUBARA[3,1]

Abstract: Oxicam-bearing non-steroidal anti-inflammatory drugs (NSAIDs) have been shown to be neuroprotective against 1-methyl-4-phenyl pyridinium in human neuroblastoma SH-SY5Y cells in our previous research. The mechanism of neuroprotection by oxicam NSAIDs was via maintenance of the phosphatidylinositol 3-kinase (PI3K)/Akt pathway independent of cyclooxygenase (COX) inhibition. The aim of this study was to establish this novel effect of oxicam NSAIDs on a mouse Parkinson's disease (PD) model using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Male C57BL/6 mice, which received MPTP (30 mg/kg/day; s.c.) for 5 consecutive days (chronic model) with 10-day follow-up saline administrations, showed significant motor dysfunction in the pole test due to reduced tyrosine hydroxylase (TH) protein levels in the brain on day 16 after MPTP/saline treatment. Daily coadministrations of meloxicam (MLX) (10 mg/kg/day; i.p.) and MPTP for the first 5 days and follow-up 10 days with MLX administrations alone (MPTP/MLX treatment) significantly ameliorated MPTP-induced behavioral abnormalities in mice. Concomitant decreases of TH protein levels in the striatum and midbrain of MPTP/MLX-treated mice were not only significantly ($p<0.01$ and $p<0.05$, respectively) ameliorated but phosphorylated Akt (pAkt473) expression in the midbrain was also significantly ($p<0.01$) increased in the midbrain when compared with MPTP/saline-treated mice. In addition, preliminary study showed that another oxicam NSAID, piroxicam, ameliorated motor dysfunction in the chronic model of Parkinson's disease. These results suggest that oxicam NSAIDs attenuated dopaminergic neuronal death in the experimental MPTP-PD model by maintenance of the Akt-signaling. Oxicam NSAIDs may serve as potential drugs for PD treatment via a novel mechanism of action.

Title: Efficacy of the HDAC1/3-targeting inhibitor, 4b, in a Huntington's disease mouse model: Involvement of the ubiquitination pathway.

Authors: H. JIA, R. KAST, *E. A. THOMAS
Dept Mol Biol, The Scripps Res. Inst., LA JOLLA, CA

Abstract: We previously demonstrated that the HDAC inhibitor, 4b, which preferentially targets HDACs 1 and 3, ameliorates Huntington's disease (HD)-related phenotypes in transgenic Drosophila and R6/2 transgenic mice. In the current study, we investigated the behavioral and biological effects of 4b at three different doses in another mouse model of HD, N171-82Q transgenic mice, and further explored potential molecular mechanisms of 4b action. Using an intermittent drug administration, we found that 4b significantly prevented body weight loss, improved several parameters of motor function and ameliorated Htt-elicited cognitive decline in HD N171-82Q transgenic mice. Pathways analysis of microarray data from the brains of 4b-treated mice revealed gene networks involving post-translational modification, including protein phosphorylation and ubiquitination pathways, associated with 4b drug treatment. Focusing on over 20 genes in these pathways, we measured expression changes in the striatum and cortex elicited by 4b at different durations of treatment using real-time qPCR analysis. We found that several genes showed significant differential regulation by 4b at different treatment time points. These included Ubiquitin-conjugating enzyme E2K (Ube2K; a.k.a. Hip2), Ubiquilin 2 (Ubqln2), Ubiquitin-conjugating enzyme E2E 3 (Ube2e3), Ubiquitin specific peptidase 28 (Usp28), BCL2/adenovirus E1B interacting protein 3 (Bnip3) and Autophagy-related 4C (Atg4c), among others. We propose that one mechanism of 4b action is associated with modulation of the ubiquitin-proteasomal and/or autophagy pathways, which might affect accumulation of the huntingtin protein.

Title: Effect of cellular stress on Huntingtin promoter function

Authors: *R. DE SOUZA, B. R. LEAVITT
Leavitt Lab., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Huntington's Disease (HD) is a neurodegenerative disorder caused by a trinucleotide repeat expansion in exon 1 of the huntingtin gene (HTT). Despite ongoing research, the function of wild-type HTT remains largely unknown. In particular, we know very little about the pathways that regulate HTT expression at a transcriptional level. Previous studies have largely focused on identifying putative transcription factor (TF) binding sites, however the effect of modulation of these TFs on HTT expression has not been explored. By understanding pathways which modulate HTT expression we can gain a better understanding of the role of HTT in normal cellular function as well as insight into the mechanisms by which mutant HTT causes HD. Previous work done by our lab has indicated that cellular stress may play a role in HTT promoter function. I have created several HEK293 cell lines which stably express HTT promoter-luciferase constructs. I have used these cell lines to test the effects of a particular type of cellular stress, hypoxia, on HTT promoter function. My preliminary results indicate that hypoxia does in fact alter HTT promoter function. In addition to hypoxia studies I will be using these cells in the future to create a high-throughput screening system to identify potential therapeutic compounds that could be used to reduce HTT expression in HD patients.

Abstract: The pathogenesis of HD is complicated and multiple pathways are compromised. Therefore attacking the problem at its root by silencing mutant huntingtin (htt) seems to be a promising therapeutic strategy to prevent subsequent pathology and delay or prevent the onset of HD. However, wild type htt is essential for brain function and therefore selectively silencing mutant and sparing wild type htt is ideal, especially when considering the fact that treatment will mostly begin early and continue throughout life.
Recent studies show that the majority of HD patients may be treatable by individualized allele-specific mutant htt silencing by targeting HD associated single nucleotide polymorphism (HD-SNPs) that are significantly enriched in the mutant HTT gene. Combinatorial analysis suggests that a panel of anti-sense oligonucleotides (ASOs) targeting as few as 3 of these HD-SNPs would provide a therapeutic option for up to 85% of the HD population. ASOs silence gene expression post-transcriptionally and can discriminate between SNP alleles anywhere in the pre-mRNA, including introns, providing flexibility to oligo design.
To generate a suitable mouse line for both in vitro and in vivo testing of ASOs, we have cross bred BACHD, YAC18 and Hdh-/-mice. The resulting humanized line, Hu97/18, is the first murine model of HD that fully genetically recapitulates human HD. We have generated a large number of ASOs targeting HD-SNP. Using primary neuronal cultures from the Hu97/18 mouse, we are currently screening these ASOs to identify those that are both potent and selective. In addition, to improve triage we have developed an assay to evaluate toxicity by measuring the cleavage of spectrin, a caspase and calpain substrate, which indicates the initiation of apoptosis. This assay allows us to exclude toxic ASOs before in vivo testing of the most promising candidates. Finally, we show that our lead ASOs can potently and selectively silence mutant htt expression in primary Hu97/18 neuronal cultures without toxicity. These results support the feasibility of an ASO mediated allele-specific mutant htt silencing strategy.
Following successful delivery and toxicity studies in mice, allele-specific mutant htt silencing may represent the most targeted therapeutic strategy for the treatment of HD and could be rapidly translated into an analogous approach for humans.

Title: Optineurin reduces mutant huntingtin aggregation

Authors: W.-C. SHEN[1,2], Y. CHERN[2,1], *B.-H. TU[2,1]
[1]Taiwan Intl. Grad. Program in Mol. Medicine, Yang Ming Univ. and Academia Sinica, Taipei, Taiwan; [2]Academia Sinica, Academia Sinica, Taipei, Taiwan

Abstract: Huntington’s disease (HD) is a neurodegenerative disease characterized by progressive cognitive, psychiatric and motor deficits which correlate with neuronal loss in the cortex and striatum. It is caused by an expansion of CAG repeat in the *Htt* gene encoding huntingtin (htt). While there are palliative therapies of HD, an effective disease-modifying treatment is still lacking. In brain of HD patients, inclusion bodies (IBs) formed by mutant htt (mhtt) are a pathologic hallmark, and correlated with onset and severity of HD. Therefore, diminishing the formation of IBs may serve as an important therapeutic strategy. Here, we demonstrated that optineurin (OPTN), colocalized with mhtt IBs both in cell models and R6/2 transgenic mice. Overexpression of OPTN reduced the number of mhtt IBs, but OPTN with the ubiquitin binding domain deleted or mutated did not. Consistently, knockdown of OPTN increased the number of mhtt IBs. Altogether, our results indicate that OPTN modulates formation or degradation of mhtt IBs.

Title: Inhibition of mutant huntingtin expression using phosphorodiamidate morpholino oligomers (PMOs)

Authors: *X. SUN, M. BHAT, Z. CORDNER, J. L. PRUITT, R. L. MARGOLIS, D. D. RUDNICKI
Johns Hopkins Univ., Baltimore, MD

Abstract: Huntington's Disease (HD) is a neurodegenerative disorder caused by a CAG trinucleotide repeat expansion in the *huntingtin* (*HTT*) gene. While the majority of evidence supports the idea that the repeat is neurotoxic at the protein level, there is growing evidence that *HTT* RNA itself is neurotoxic and that the gene antisense to *HTT* (*HTTAS*) may also be involved in disease pathogenesis. Use of antisense oligonucleotides (ASOs) to suppress HTT expression is an attractive therapeutic strategy that could address both protein and RNA toxicity. ASOs targeted to the CAG repeat region are of special interest due to their ability, at least in part, to discriminate between normal and expanded *HTT*. Compared to other types of ASOs, phosphorodiamidate morpholino ASOs (PMOs) are very stable, highly soluble and non-toxic to cells even at high concentration. We therefore designed PMOs targeted to either the *HTT* CAG repeat or to regions outside of the repeat and tested their ability to suppress HTT expression. Control and HD patient-derived fibroblasts with 44, 77 or 109 CAG repeats were treated for 48 hours with repeat-targeting (CTG)n PMOs of different lengths or with PMOs targeting sequence outside of the repeat region, and mutant and normal HTT protein expression was measured. (CTG)n PMOs preferentially suppressed mutant HTT protein, dependent both on the length of CAG repeat in the HD fibroblasts and the length of the PMOs. As predicted, PMOs targeted to regions 5' of the *HTT* repeat reduced normal and expanded HTT protein expression without any effect on protein and RNA expression of endogenous control genes. These preliminary results demonstrate the potential of PMO therapy. While targeting the HD repeat region results in allele specificity, targeting non-repeat regions minimizes off-target effects. We are currently testing other PMOs in HD cell models, and the effect of PMOs in mouse models of HD.

Title: Transcriptional dysregulation in Huntington's Disease induced pluripotent stem cells

Authors: M. CASALE, *A. R. KING, S. WINOKUR, J. STOCKSDALE, N. JACKSON, M. VAWTER, P. DONOVAN, L. LOCK, L. THOMPSON
Univ. of California, Irvine, Irvine, CA

Abstract: Understanding the underlying mechanisms that contribute to Huntington's disease (HD) and the identification of molecular signatures as indicators for pathogenesis are of importance to the development of preventative therapies. Human induced pluripotent stem cells (iPSC) offer an opportunity to use a genetically relevant representation of disease in culture with the expanded CAG repeat expressed within the normal endogenous locus. Transcriptional dysregulation in the brain appears to represent an early and central mechanism in HD pathogenesis. As part of an HD iPS Consortium, we have demonstrated that differentiated HD lines show CAG expansion-associated gene expression patterns in HD versus control neural stem cells (NSC) using microarray techniques. Hierarchical clustering of the most significant genes showed a clear separation of HD and control NSC datasets. Of the statistically significant gene changes, key pathways were identified using Ingenuity Pathway Analysis (IPA) and the results showed patterns of altered expression consistent with known HD changes in specific genes and proteins. In addition, this analysis provided identification of novel genes, functional categories and pathways impacted by the mutant full-length Huntingtin (Htt) protein. Several key pathways emerged, including altered G protein coupled receptor networks. Further, alterations in the innate immune response and glucocorticoid signaling were observed, providing evidence of an early inflammatory phenotype. Evidence was also found for the activation of adaptive immunity, including the extravasation of cytotoxic T-Cells across the blood brain barrier. Inflammation in the brain is a well-established feature of neurodegenerative diseases, including HD. Early detection of inflammatory cytokines IL-6, IL-8, and TNF-α in CSF and brain has been observed from HD mouse models and in CSF from HD patients (Bjorkqvist et al., 2008). Such increases may have either neuroprotective or detrimental effects. The glucocorticoid receptor (GR) pathway, which plays a major role in anti-inflammatory responses, has also been implicated in HD. Specifically, the serum and glucocorticoid activated kinase (SGK) phosphorylates Htt on S421 in a manner which is neuroprotective (Rangone et al., 2004). Although these proposed

mechanisms are likely playing a role in HD pathogenesis, our current understanding of immune responses and neuroinflammation in HD is limited, therefore iPS cells provide a powerful system to delineate the distinct roles of these processes through stages of neuronal development and in specific cell lineages.

Title: Somatostatin receptors-mediated inhibition of nmda currents and dissociation of nmdars complex in striatum: Implication in excitotoxicit

Authors: P. S. RAJPUT[1], B. YANG[2], B. R. SASTRY[2], *U. KUMAR[1]
[1]Fac. of Pharmaceut. Sciences, Univ. of British Columbia, Vancouver, BC, Canada; [2]Dept. of Anesthesiology, Pharmacol. and Therapeut., The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Overactivation of N-methyl-D-aspartate receptors (NMDARs) in heteromeric complexes play a crucial role in excitotoxicity that is associated with several neurodegenerative diseases. Recently, intense efforts have been made to minimize the risk of NMDA induced excitotoxicity. In the present study we used the combination of morphological, biochemical and electrophysiological techniques to characterize the role of somatostatin receptor 1 and 5 (SSTR1 and SSTR5) on NMDA induced changes in rat brain stratum. Here we show that the activation of SSTR 1 and 5 disrupt NMDARs complex formation and modulate signaling pathways associated with neuronal degeneration in the striatum. SSTR1 and SSTR5-specific agonist in combination exert pronounced inhibitory effect on NMDA currents and decreases the expression of PSD-95, calpain and enhanced CREB phosphorylation indicating the activation of synaptic NMDA receptor which correlates with dissociation of NMDARs complex as well as inhibition of NMDA

current upon SSTR activation. SSTR1 and SSTR5 agonist suppress downstream signaling pathways and modulate DARPP-32 phosphorylation at Thr34 and Th75 position. In conclusion, our results establish SSTR1/5 as a promising therapeutic strategy in dissociation of NMDARs heteromeric complex and abrogating cell death promoting signaling in striatum.

Title: Behavior assessments in children at risk for huntington's disease

Authors: *J. LEE[1], A. CONRAD[1], J. S. PAULSEN[1], E. EPPING[1], L. C. RICHMAN[2], P. NOPOULOS[1]
[1]Psychiatry, [2]Pediatrics, Univ. of Iowa, Iowa City, IA

Abstract: Huntington's disease (HD) is an autosomal dominant disease caused by an expansion of greater or equal to 39 CAG repeats on the gene encoding for the huntingtin protein (*HTT*). Although the primary neuropathology is that of neurodegeneration of the striatum, mutant huntingtin (*mHTT*), which is present throughout the life span, may also affect normal brain development. In the current study, the effect of *mHTT* on neural development was examined by evaluating the behavior of children (7-18 years of age) at risk for HD (no juvenile HD included). Parental ratings on two standardized questionnaires, Pediatric Behavior Scale (PBS) and Behavior Rating Inventory of Executive Function (BRIEF), were assessed in order to evaluate problems in behavior and behavior regulation of the participants. Behavioral measurements of children tested as gene-expanded (n=29, CAG repeats $\geq$ 39) or gene non-expanded (n=30, CAG repeats $\leq$ 39) as a result of presymptomatic gene assessment (for research purposes only) were compared to those of a large number of healthy children matched for age and sex. The results showed that gene-expanded children, but not gene non-expanded children, had significantly more disruption in behavior when compared to healthy peers. Gene-expanded children showed significantly more problems in measures of Opposition, Explosiveness, Impulsivity, Hyperactivity and Inattention within PBS. Specific indices of executive function in which gene-

expanded children showed significantly more disruption include: Shifting, Initiation, Working Memory, Planning/Organizing and Monitoring as measured by BRIEF. The significant increase, as compared to healthy controls, in disrupted behavior in children who are estimated to be decades ahead of HD diagnosis may reflect early influence of *mHTT* on normal neural developmental process. Investigation of subtle but persistent effects of *mHTT* on gene-carriers may further our understanding of the pathogenesis of HD and thereby lead to the development of effective early intervention.

Title: Astrocyte conditioned medium enhances neuronal maturation of iPS derived cultures: Role of GABAA evoked Ca2+ influx.

Authors: *D. J. RUSHTON[1], H.-E. TSENG[1], V. B. MATTIS[2], C. N. SVENDSEN[2], N. D. ALLEN[1], P. J. KEMP[1]
[1]Sch. of Biosci., Cardiff Univ., Cardiff, United Kingdom; [2]Regenerative Med. Inst., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Astrocytes promote synaptogenesis *in vitro*, a development which may be crucial to generating appropriate stem cell derived models of neurodegenerative diseases. However, the mechanisms by which they exert such effects are currently unknown.
We investigated the influence of mouse striatal astrocyte conditioned medium during the time course of differentiation and maturation of human iPS-derived neuroprogenitors, as described in [1], using whole-cell patch-clamp and Ca^{2+} imaging. Although the proportion of cells able to fire an action potential in response to depolarization was unaffected, the conditioned medium evoked: i) significant hyperpolarization of the membrane at rest; ii) upregulation of L-, N- and R-type Ca^{2+} channel function, and; iii) a dramatic increase in the proportion of spontaneously active cells.

Increasing the extracellular [Ca^{2+}] from 0.6 to 1.8 mM resulted in accelerated neurogenesis and mimicked the enhanced maturity seen with astrocyte conditioned medium. These effects were blocked using specific inhibition of N- and L- type Ca^{2+} channels or $GABA_A$ receptors. Taken together, these data demonstrate a clear role for $GABA_A$-evoked depolarization, and consequent voltage-gated Ca^{2+} influx, in the process of neuronal maturation, and suggest that astrocytes may promote synaptogenesis, at least in part, via increased gain of the GABA excitation pathway.

Abstract: White matter alterations occur at early stage in Huntington's disease (HD), an autosomal neurodegenerative disorder characterized by severe motor, behavioral and cognitive symptoms, and degeneration in basal-ganglia-thalamo-cortical circuits may play important role in clinical HD. In R6/2 mouse model of HD, we have previously shown extensive diffusion tensor imaging (DTI) changes at the age of 12 wks using *ex vivo* high-resolution 3D DTI with group-level whole brain statistical analysis method, tract based spatial statistics (TBSS). We showed decreased fractional anisotropy (FA) bilaterally in lateral septal areas, external capsule,

corpus callosum and in the dentate gyrus, as well as in various different bilateral thalamic and hypothalamic nuclei e.g. parafascicular, lateral posterior and mediodorsal thalamic and dorsomedial hypothalamic nuclei.
In this study, we performed extensive histological assessment of R6/2 and WT mice at 12 wks to corroborate the DTI findings for microstructural white matter pathologies. Nissl and gold chloride stainings were used as basic stainings to evaluate cytostructural and myelin alterations, and amyloid precursor protein (APP) immunohistochemistry was used to assess axonal damage. Myelin was assayed with Myelin Basic Protein (MBP) immunohistochemistry. Systematic analysis of MBP sections from wild-type and transgenic mice in anatomical areas displaying changes in FA after the TBSS analysis did not indicate significant wide-spread white matter damage difference in transgenic animals. Similarly, APP and Nissl staining analyses did not reveal major structural changes.
Generally, myelin has been considered to be one of the major tissue components contributing to restricted water diffusion in tissue. However, these data suggests that myelin sheath may not be the main contribution to the changes in water diffusion in transgenic animals, and diffusion of water may also be restricted by structures such as neuronal cell bodies, dendrites or glia. Moreover, TBSS analysis of R6/2 mice changes were also in grey matter structures with low content of myelinated fibers, such as the lateral septum, paraventricular thalamic nuclei, mediodorsal thalamic nucleus or dentate gyrus. In summary, these findings suggest that DTI changes are not related to axonal damage or wide-spread
degradation of white matter but may be associated with other microstructural alterations which need further investigation.

Title: Early postnatal deficiency of huntingtin-associated protein 1 leads to depressive behavior in adult mice

Authors: *J. XIANG[1], H. YANG[2], S. LI[1], X.-J. LI[1]
[1]Human Genet., Emory Univ., Atlanta, GA; [2]Inst. of Neurosciences, The Fourth Military Med. Univ., Xi'an, China

Abstract: Huntingtin-associated protein 1 (Hap1) is an intriguing neuronal protein that interacts with several disease-causing proteins such as huntingtin and Ahi1, whose mutations lead to Huntington's disease and Joubert syndrome, respectively. Germline knockout (KO) of Hap1 in mice results in early postnatal death due to depressed feeding behavior. Hampered by this early lethality and lack of animals surviving into adulthood, the role of Hap1 in the adult mice remains to be investigated. To gain insight into this question, we utilized tamoxifen-inducible Cre-Loxp system to generate an inducible Hap1 KO mouse model in which Hap1 can be depleted significantly after tamoxifen injection. This model allows us to deplete Hap1 at different ages and therefore test the role of Hap1 at various stages of development and in the adults. By inducing Hap1 KO at early postnatal days, we observed growth retardation, a phenotype that is similar to that of germline Hap1 KO mice. Interestingly, these mice when grown to adults exhibited depressive behavior as examined by forced swimming and tail suspension tests, a phenomenon that is consistent with the previously reported observation in Ahi1 KO mice. Moreover, this phenotype can be recapitulated in adult camk2a-Hap1 conditional KO mice, in which Hap1 deletion occurs postnatally, and is most prominent in the cortex and hippocampus. The depressive behavior can be rescued when these mice were given antidepressant drug imipramine. To further examine the mechanism underlying this phenomenon, we tested hippocampal neurogenesis after Hap1 depletion, and found that early Hap1 KO resulted in a reduction in BrdU incorporation in the dentate gyrus. The deficit in neurogenesis was not seen when Hap1 was depleted at a later developmental stage but could be detected in camk2a-Hap1 KO mice. This study suggests that Hap1 is required for postnatal neurogenesis, a mechanism that may underlie depressive phenotypes of Hap1 KO mice.

Title: Neurochemical correlates of disease progression in subjects with pre-manifest and early Huntington disease: a ^{1}H magnetic resonance spectroscopy study

Authors: J. M. PADOWSKI[1], K. E. WEAVER[1], T. RICHARDS[1], K. E. CONLEY[1], *N. M. KLEINHANS[1], E. H. AYLWARD[2]
[1]Dept Radiology, Univ. Washington, SEATTLE, WA; [2]Seattle Children's Res. Inst., SEATTLE, WA

Abstract: Objective. Atrophy of the caudate nucleus occurs in Huntington disease (HD), and reduced caudate volume precedes onset of clinically-observable motor, cognitive and psychiatric dysfunction by at least a decade. Animal models and postmortem studies suggest a preferential loss of neurons relative to other cell types in the caudate during HD. This study was undertaken to test whether (1) neurochemical changes are related to reduced caudate volume in HD, and (2) the specific neurochemical changes support the hypothesis that a disproportionate loss of neurons occurs in the pre-manifest to early stage of HD.
Methods. Single voxel proton magnetic resonance spectroscopy (^{1}H MRS) at 3T was used to determine neurochemical concentrations in the left caudate of 10 subjects with pre-manifest to early HD and 10 age- and gender-matched controls. Concentrations of N-acetyl aspartate (NAA), creatine, choline, myo-inositol, glutamate and glutamate + glutamine (GLX) were quantitated relative to unsuppressed water signal with LCModel software. MRI was used to determine the volume of the left caudate in all subjects.
Results. We identified a series of neurochemicals, detectable by ^{1}H MRS, that evidenced reduced concentration in association with smaller caudate volume in subjects with the HD gene. Concentrations of NAA ($p<0.01$), creatine ($p<0.05$), choline ($p<0.01$), GLX ($p<0.05$), and glutamate ($p<0.05$) were significantly correlated with caudate volume in HD gene-carrying subjects. NAA and creatine also correlated with disease burden (a function of CAG repeats and age; $p<0.05$). No difference in caudate neurochemical concentrations between controls and HD gene-carrying subjects was detected (*t*-test).
Conclusions. The new insight provided by these results is that a decrease in concentration of a suite of neurochemicals accompanies loss of caudate nucleus volume. The relationship in HD gene-positive subjects between decreased caudate volume and decreased mass of NAA (a neuronal marker) per unit caudate volume suggests that neurons indeed may be lost disproportionately, consistent with animal models of HD and postmortem studies demonstrating spiny neuron loss in the caudate during HD progression. The relationship between decreased concentrations of creatine, choline, GLX and glutamate and decreased caudate volume in subjects with the HD gene suggests that additional qualitative changes in cellular composition occur during HD progression. The results of this study indicate that ^{1}H MRS can be used to

explore fundamental relationships between neurochemical and brain structural changes in subjects with pre-manifest to early HD.

Abstract: Huntington’s disease (HD) is a genetic neurodegenerative disorder caused by a trinucleotide repeat expansion mutation in exon 1 of the *HTT* gene encoding protein huntingtin. Dramatic loss of medium spiny neurons is typically observed in the striatum of HD patients, with more moderate loss of other neurons. Recently, as a part of the HD iPSC Consortium, we generated and characterized human iPS cell lines with an allelic series of HD mutations. We have demonstrated HD specific phenotypes such as increased toxicity in HD (109 and 180 CAG) versus control (21 and 33CAG) iPS cells under oxidative stress and autophagy inhibition stress in cells differentiated towards neurons positive for markers of striatal medium spiny neurons, including DARPP32 and BCL11B. We have also shown that maintenance of differentiated cells in neural induction medium alone (without BDNF) for 48 hours resulted in increased toxicity in a CAG expansion dependent manner. Here, we report that BDNF and 7,8-dihydroxyflavone (7,8-DHF), a small molecule reported to activate the high affinity BDNF receptor (TrkB) can rescue BDNF withdrawal induced toxicity in the HD iPSC model. We demonstrate 7,8-DHF dose-dependent decrease of cell death in differentiated HD iPS cells. BDNF withdrawal induced toxicity is significantly higher in the DARPP32-positive differentiated HD iPSC population

versus DARPP32-negative cell population. However, we also did find an increase of cell toxicity in DARPP32-negative cells in a CAG expansion dependent manner, indicating that cells other than DARPP32 positive neurons can be affected by the *HTT* mutation. We have also continued identification of markers associated with expression of mutant Htt using iTRAQ (isobaric tags for relative and absolute quantification), a method of quantitative proteomics analysis. We observed a polyQ length-dependent increase in expression of several neuronal proteins, such as FABP7 and CRMP1, and a decrease in expression of the RNA-binding protein FUS/TLS, and confirmed by Western Blotting. Further validation of these and other candidate proteins emerging from proteomics studies will involve RNAi silencing and toxicity assays and analysis of HD iPS cells differentiated into striatal medium spiny neurons.

Abstract: Huntington’s disease (HD) is caused by expression of a mutant form of huntingtin (Htt) protein. One possible treatment for HD may be to reduce expression of mutant Htt in the brain via RNA interference. Unless the therapeutic molecule is designed to be allele-specific, both wildtype and mutant protein will be suppressed by RNA interference treatment. Whether Htt performs essential functions in the adult brain is unclear. Here, we report that the adult primate brain can tolerate moderately reduced levels of wildtype Htt protein for an extended

period of time. A serotype 2 adeno-associated viral vector encoding for a short hairpin RNA (shRNA) targeting rhesus Htt mRNA (active vector) was bilaterally injected into the striatum of four adult rhesus monkeys. Four other animals received a comparable vector encoding a scrambled control shRNA (control vector). General health and behavior were monitored for six months at which point brain tissues were sampled and assessed blindly for Htt mRNA and protein knockdown as well as for neuropathology. Reduction in wildtype Htt mRNA levels averaging about 30% was measured by qPCR in the striatum of active vector recipients six months post-injection relative to controls. Reduction in Htt protein levels was also observed in these animals relative to controls, with an average protein reduction in the putamen of about 45% measured by Western blot analysis. As with control vector recipients, no adverse effects were observed behaviorally, and no neurodegeneration was found on histological examination of active vector recipients. Our results suggest that long-term partial suppression of wildtype Htt may be safe. Thus, if a comparable level of suppression of mutant Htt is beneficial, then partial suppression of both wildtype and mutant Htt may result in a net benefit in heterozygous HD patients.

Abstract: A major issue for modeling adult onset diseases such as Huntington's disease (HD) using induced pluripotent (iPS) cells concerns the age and maturity of in vitro generated neurons that may be required to observe disease- associated phenotypes. A necessity for complex and extended neural differentiation and culture protocols also has implications for efficient assay development. Here we have used a simple and rapid differentiation protocol in which iPS cell-derived neural stem cells are plated and differentiated over a 2-4 week period. In this time frame neurons express markers of neuronal maturation such as MAP-2, Synaptophysin and striatal markers such as CALRETININ, CALBINDIN and express functional neuronal properties including evoked and spontaneous action potential generation. Importantly, these cultures are suitable for high content phenotypic screens.
Using this protocol, we differentiated HD iPS cell lines and established assays to investigate disease relevant phenotypes. Firstly, we have used an automated imaging system that follows individual mature neurons and tracks cell survival over time. Our imaging techniques determine multiple cellular parameters that are analyzed with powerful statistical approaches that confer high sensitivity (Arrasate et al., 2004; Arrasate and Finkbeiner, 2005). Secondly we have used fura-2 ratiometric Ca2+-imaging to examine Ca2+ dyshomeostasis in neurons in response to glutamate stimulation across cell populations on a cell by cell basis.
Significantly, results show that CAG-associated phenotypes manifest in rapidly differentiated neurons and do not necessarily require long and elaborate differentiation protocols to be used to be relevant to HD. We are extending our assays to study mechanisms of disease and investigate strategies for neuroprotection. We are evaluating the effects of several trophic factors and autophagy inducers on survival and will report our results.

Title: Mutant huntingtin in immune cells tracks Huntington's disease progression

Authors: *R. ANDRE[1], A. WEISS[2], U. TRAEGER[1], S. GRUENINGER[2], R. FARMER[3], C. LANDLES[4], R. I. SCAHILL[1], D. MACDONALD[5], C. FROST[3], G. P. BATES[4], G. BILBE[2], R. KUHN[2], E. WILD[1], S. J. TABRIZI[1]

London, London, United Kingdom; [5]CHDI Management/CHDI Fndn., Los Angeles, CA

Abstract: Huntington's disease (HD) is a fatal, inherited neurodegenerative disorder caused by an expanded CAG repeat in the gene encoding huntingtin (*HTT*). Mutant HTT expression in the central nervous system (CNS) is the primary pathogenic factor for the development of HD, with increasing expression levels associated with disease severity and toxicity. However, the importance of the peripheral immune system in neurodegenerative disease is becoming increasingly recognized. Peripheral immune system dysfunction in HD includes increases in innate immune proteins in patient plasma, many of which track with disease progression.
Inflammatory cytokines and chemokines are elevated in the plasma of HD patients, the origin of which appears to be hyper-reactive monocytes carrying the HD mutation. The hyper-reactivity observed in monocytes is reflected by a similar pattern in HD microglia and microglial activation is seen before symptom onset in HD mutation carriers. These effects appear to be due to the cell intrinsic expression of mutant huntingtin (mHTT), the effects of which on intracellular signalling pathways are being investigated by expressing and knocking-down both mutant and wild-type HTT. Therapeutic approaches to lower mutant mHTT levels are expected to proceed to human trials soon, but non-invasive quantification of mHTT is not currently possible. HTT levels in peripheral immune cells have not been quantified before. A recently described time-resolved Förster resonance energy transfer (TR-FRET) immunoassay was used to quantify mutant and total HTT protein levels in HD

patient leukocytes. Mean mHTT levels in monocytes, T cells and B cells differed significantly between HD patients and controls, and between pre-manifest mutation carriers and those with clinical onset. Monocyte and T cell mHTT levels were significantly associated with disease burden scores and caudate atrophy rates in HD patients. Mutant HTT N-terminal fragments detected in HD monocytes may explain the progressive increase in mHTT levels in these cells. These findings indicate that quantification of mHTT in peripheral immune cells by TR-FRET holds significant promise as a non-invasive disease biomarker. More broadly, peripheral immune
dysfunction may be pathogenically important in HD and could offer a window onto relevant CNS events.

Title: A novel *in vitro* and *in vivo* system to study Huntington's disease using iPS cells

Authors: *V. B. MATTIS[1], J. A. KAYE[2], S. FINKBEINER[2], C. N. SVENDSEN[1]
[1]RMI, Cedars-Sinai, Los Angeles, CA; [2]Gladstone, UCSF, San Francisco, CA

Abstract: Huntington's disease (HD) is an autosomal dominant disorder caused by expansion of polyglutamine (CAG) repeats in the huntingtin gene leading to loss of striatal and cortical neurons and deficits in coordinated movements and cognition. Transgenic rodent models are valuable for testing cell death mechanisms and therapeutic intervention. However, mouse and rat models may not fully represent the human condition. Therefore, we, in collaboration with the HD iPSc consortium, have recently reported a new in vitro model of HD based on the generation of induced pluripotent stem cells (iPSCs) from subjects with between 60 and 180 CAG repeats and controls. CAG repeat expansion had no obvious effects on reprogramming, neural stem cell

(NSC) production, or the generation of neurons. However, HD and control iPS cell lines showed differential risk of cell death, specifically upon BDNF withdrawal.
We therefore wanted to use this novel HD model to study the roles of BDNF in HD iPSCs. Specifically, we wanted to elucidate the mechanisms of cell death in for continued validation of this iPSC HD model and with the hope of gaining important insight into HD for future therapeutic targets. Additionally, by transplanting striatal neurons differentiated from HD iPS cells into the striatum of neonatal mice, cells will integrate and mature, allowing us to study them in vivo. This will also allow us to study non-cell autonomous effects of HD and generate a novel "humanized" HD mouse model.

Title: Biomarker assays for Huntington's Disease: Detection of human and mouse huntingtin proteins using the meso scale discovery platform

Authors: M. A. TESSARI[1], I. BOOGAARD[1], M. SMITH[2], K. PULLI[1], A. SZYNOL[1], F. ALBERTUS[1], S. GRIFFIOEN[1], M. B. A. C. LAMERS[2], C. ESSRICH[1], G. MCALLISTER[2], I. MUNOZ-SANJUAN[3], *D. F. FISCHER[4], D. MACDONALD[3]
[1]Galapagos, Leiden, Netherlands; [2]BioFocus, Saffron Walden, United Kingdom; [3]CHDI Fndn., Los Angeles, CA; [4]BioFocus / Galapagos, Leiden, Netherlands

Abstract: Huntington's disease (HD) is caused by an expansion of a CAG triplet repeat in the huntingtin (Htt) gene, resulting in expression of an expanded poly-glutamine (polyQ) tract in the N-terminal region of the Htt protein. RNAi technology aiming to reduce the amount of Htt protein has shown considerable potential for the treatment of HD. Therefore, robust biomarker assay read-outs for expanded and non expanded Htt protein levels will be essential for both pre-clinical and clinical validation of such novel therapies.
BioFocus, in collaboration with the CHDI Foundation, is developing a panel of ELISA-based Meso Scale Discovery (MSD) electrochemiluminescence assays to enable the detection of non-expanded and polyQ-expanded Htt in cellular, rodent, and clinical biosamples. Here we describe three of these assays: 1) a pan human Htt assay that detects non-expanded and polyQ-expanded

Htt proteins, 2) a polyQ-expanded human Htt assay for mutant Htt protein, and 3) a mouse/rat Htt specific assay that detects endogenous Htt proteins in disease relevant rodent models. These assays are highly sensitive (detecting fmols of protein) and robust as they are able to measure Htt levels in a variety of complex biological samples. As a proof-of-concept, we will show examples of Htt protein detection in brain tissue of transgenic rodent HD models and quantification of both transgenic and endogenous proteins utilizing purified recombinant Htt proteins as a standard. These assays represent an essential and versatile tool to assess the efficacy of Htt suppression therapeutic strategies and will contribute to the validation and development of such novel therapies for HD.

Title: The C9orf72 ALS mutation causes both increased expression and aberrant splicing of the endothelin-B receptor, and its ligand endothelin-1 is increased in CNS tissue from ALS patients and mutant mice.

Authors: *L. W. OSTROW[1], C. DONNELLY[1], Y. LI[1], S. VIDENSKY[1], P. TIENARI[2], N. J. MARAGAKIS[1], B. J. TRAYNOR[3], J. D. ROTHSTEIN[1]

Abstract: Endothelin-1 (ET-1, gene symbol EDN1) and the endothelin-B receptor (ET_B, gene symbol EDNRB) are upregulated in reactive astrocytes. ET_B receptor expression is also increased on spinal motor neurons in animal models of peripheral nerve and spinal cord injury. Astrocyte reactivity/dysfunction is implicated in ALS pathogenesis, and ET-1 expression is upregulated in the motor cortex of human autopsy specimens from sporadic ALS patients. The recently discovered *C9orf72* mutation is found in >30% of familial ALS cases, and has been reported in 4-10% of sporadic ALS cases. The function of the C9orf72 protein is unknown. Like other non-coding repeat expansion mutations, C9orf72 mutation based toxicity may be due to aberrant RNA splicing. We have generated fibroblast cell lines from ALS patients with the C9orf72 expansion and normal controls. ET_B receptor expression is increased > 2-fold in fibroblast cell lines derived from C9orf72 patients compared to normal controls, and the EDNRB gene shows significant aberrant exon splicing. The increased expression and aberrant splicing pattern recapitulate published results on ET_B receptor gene expression and splicing abnormalities described in motor-neuron enriched mRNA from human ALS autopsy spinal cord tissue. Furthermore, our preliminary data suggests C9orf72 siRNA can knock down ET_B receptor gene expression in the fibroblasts. Additionally, we have demonstrated by ELISA that the ET-1 peptide is increased in spinal cord tissue from SOD1 ALS mutant mice compared to wild-type littermates, and in human ALS autopsy tissue from CNS regions involved in ALS. In aggregate, these studies in SOD1 ALS mice and human ALS patient-derived cell lines and autopsy tissues suggest that alterations in the endothelin system could contribute to ALS pathogenesis. Further investigations into this pathway and its relevance to motor neuron toxicity are now warranted.

Title: Characterization of the ALS-linked C9ORF72 gene in NSC34 cells and patient lymphoblasts

Authors: *X. WEN, W. TAN, A. BOGUSH, P. PASINELLI, D. TROTTI
Dept. of Neurosci., Thomas Jefferson University- Farber Inst. For Neurosciences, Philadelphia, PA

Abstract: Amyotrophic lateral sclerosis (ALS), a progressively fatal neurodegenerative disease of upper and lower motor neurons, has recently been the subject of major advances, especially in relation to frontotemporal dementia (FTD) subtypes and shared pathogenic mechanisms. Two independent groups have identified an expansion of GGGGCC hexanucleotide repeats (G4C2) located in the non-coding region of the first intron of the C9ORF72 gene as the most common cause of ALS and FTD identified to date. Based on the initial analysis of this region, normal individuals usually carry up to 23 repeated G4C2 repeats, whereas affected individuals carry repeat expansions that may be up to 10 Kb, containing over 1,000 repeats. C9ORF72 encodes a highly conserved alternatively spliced 481 amino acid protein (full length) and a much shorter 222 amino acid transcript, both of unknown biological function. Here, we have successfully characterized antibodies, shRNA, siRNA and plasmids for studying the function and localization of C9ORF72. We also generated stable knock-down cell lines for C9ORF72 to study its cellular functions. Preliminary results suggest that this protein is up-regulated in differentiated NSC-34 cells and possibly involved in stress response. However, by stably knocking down C9ORF72 in NSC-34 cells, these cells do not display any significant morphological differences compared to controls when differentiated into motor neurons. By using immunofluorescence and subcellular fractionation, we show that C9ORF72 is a cytosolic protein with some perinuclear localization pattern, possibly associated with ER or stress granule. Immunoprecipitation results also reveal its ability to oligomerize with itself and across isoforms, which may suggest its ability to form protein complex with RNA or other proteins. Using the antibodies that we characterized with the knock-down NSC34 cells, we also demonstrated that in lymphoblast cell line of a C9ORF72 expanded repeat carrier, the protein levels of C9ORF72 isoform a is decreased compared to the control lymphoblast cell line. Experiments are undergoing to further characterize the cellular functions of C9ORF72 and its potential role in ALS.

Title: Analysis of the C9ORF72 hexanucleotide repeats size in ALS patient derived fibroblasts, iPS cells and postmortem brain tissues

Authors: *P.-W. ZHANG[1], C. DONNELLY[1], R. SATTLER[1,2], L. OSTROW[1], U. BALASUBRAMANIAN[1], N. MARAGAKIS[1], J. ROTHSTEIN[1,2]
[1]Dept. of Neurol., Johns Hopkins Univ. Sch. of Med., BALTIMORE, MD; [2]Brain Sci. Inst., Baltimore, MD

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disease with familial transmission in about 10% of the cases. Mutations in SOD1 encoding the cooper/zinc superoxide dismutase, TARDBP (TAR DNA-binding protein 43) and FUS (fused in sarcoma) are responsible for 20%-30% of familial ALS disease. Rare mutations in other genes like ANG, VAPB, DAO, OPTN, VCP and UBQLN2 have been reported. Recent studies have identified expanded GGGGCC hexanucleotide repeats in the C9ORF72 gene in ALS, frontotemporal dementia (FTD) and ALS-FTD. This novel mutation is currently the most common genetic cause of familial ALS (23%-47%) as well as sporadic ALS (4%-21%) in the USA, Belgium and Finland. Characterization of the role of repeat length and tissue distribution effects of variation in repeat expansion size in the C9ORF7 gene is suggested to be crucial for the understanding of the mechanisms and pathways of ALS pathology.
Here we report data on the repeat size in the C9ORF72 gene in different cell types and tissue samples obtained from ALS patients. Using an optimized Southern Blotting approach, the size and number of repeats were determined in fibroblasts and iPS cell lines derived from ALS patients with C9ORF72 repeat mutations. All of the repeats were over 3 kb long and one repeat number was found to contain over 1,000 repeats. Interestingly, the size and number of repeats in the iPS cell lines were different from the fibroblasts derived from the same patients. We also examined the dynamic changes in the repeat size as cell lines underwent increasing passages. Finally we analyzed repeat lengths in multiple different brain regions from more than six C9ORF72 autopsies.

Title: PIKK dependent phosphorylation induces nuclear-cytoplasmic translocation of FUS

Authors: *Q. DENG[1,2], K. HUDSON[1], G. TAYLOR[1], D. DUONG[2,3], N. T. SEYFRIED[2,3], D. ITO[5], T. KUKAR[1,4,2]

Abstract: Mutations in TARDBP (TDP-43) and the Fused in sarcoma (FUS) gene have been identified that cause inherited and sporadic forms of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). TDP-43 and FUS are both DNA/RNA-binding proteins with striking structural and functional similarities. Both TDP-43 and FUS are predominantly found in the cell nucleus. In disease, however, TDP-43 and FUS have been observed to redistribute to the cytoplasm and accumulate in neuronal cytoplasmic inclusions. Post-translational modifications (PTMs) including cleavage, ubiquitination, and phosphorylation have been described as markers of pathological changes in TDP-43 proteinopathies. To date, similar PTMs of FUS have not been described in cases with pathological FUS changes. In the course of studying the cell biology of FUS, we have discovered that FUS undergoes phosphorylation. A combined approach using small molecule kinase inhibitors and phospho-specific antibodies revealed that FUS is phosphorylated at serine and threonine sites by DNA-dependent protein kinase and Ataxia telangiectasia mutated (ATM) kinase. We examined a series of truncated FUS mutants and narrowed down the N-terminus as the primary site of phosphorylation. Mass spectrometry experiments are underway to map the precise sites of FUS phosphorylation. Experiments in cells suggest that phosphorylation of FUS plays a critical role in regulating import and export of FUS between the nucleus and cytoplasm. Because accumulation of FUS in neuronal cytoplasmic inclusions is a pathological hallmark of some ALS and FTD cases, our data suggests that deregulation of FUS phosphorylation may play an important role in disease pathogenesis. Furthermore, FUS phosphorylation could be a viable drug target for ALS and FTD therapies.

Title: Expression of truncated FUS/TLS protein triggers proteinopathy in cultured cells and transgenic mice

Authors: T. A. SHELKOVNIKOVA[1,2], N. CONNOR-ROBSON[1], A. DEIKIN[3], O. PETERS[1], H. ROBINSON[1], E. R. SADCHIKOVA[3], V. BUCHMAN[1], *N. N. NINKINA[1,2]

Abstract: Pathological inclusions formed by aggregated FUS or TDP-43 proteins have been recently identified as characteristic features for a number of neurodegenerative conditions. These DNA/RNA-binding proteins share
striking structural similarity, though the sequence of domains in FUS is
inverted to those in TDP-43. It is well established that ~25 kDa highly
aggregate-prone C-terminal fragments of TDP-43 are common components of pathological protein aggregates. We hypothesized that expression of a structurally similar fragment of FUS, i.e. the C-terminally truncated form, comprising intact prion-like domain but disrupted RNA-binding region and lacking nuclear localization signal (NLS), might also yield robust proteinopathy in vivo. In cell culture studies we demonstrated that truncated human FUS is highly aggregate-prone and forms aggresome-like structures. This is in contrast to other modified forms of FUS localizing in the cytoplasm due to the lack of functional NLS that become recruited into stress granules. To assess if expression of C-terminally truncated FUS would trigger proteinopathy in vivo, we used a Thy1 promoter expression cassette to generate transgenic mice. Mice expressing truncated human FUS in the nervous system developed early onset and fast progressing motor dysfunction that caused severe disability and premature death. Abundant FUS-positive inclusions were detected in lower motor neurons of symptomatic transgenic mice, some of which were ubiquitinated. FUS proteinopathy was accompanied by neuroinflammatory changes, neurofilament disturbances, loss of nerve fibers and muscle denervation. The mice demonstrated decreased numbers of lower motor neurons both in spinal cord and selected motor nuclei of brainstem. Results of our studies demonstrate that expression of truncated FUS loosing both nuclear localization and RNA-binding ability triggers proteinopathy in cultured cells and in mice. Pathological changes developed in the nervous system of transgenic mice recapitulate many characteristic features of human ALS pathology. These models will be useful for getting further insights into mechanisms and consequences of FUS proteinopathy in humans and testing novel therapeutic interventions.

Title: ALS mutants of FUS/TLS may influence the function of a neuroprotective long non-coding RNA

Authors: J. LAWSON[1], B. ZHANG[2], F. JAHANIANI[2], L. GUNAWARDANE[2], *L. J. HAYWARD[1], S. VALADKHAN[2]

Abstract: Mutations in FUS/TLS, a protein with a diverse range of functions in cellular RNA metabolism, are associated with familial cases of amyotrophic lateral sclerosis (ALS), suggesting that disturbances in RNA processing may contribute to the development of this disease. We have studied the function of a long non-coding RNA (lncRNA-1) which is almost exclusively expressed in neurons, including anterior horn neurons. lncRNA-1 is induced in response to a variety of stressful stimuli including oxidative and ER stress in neuronal cells. To determine if the stress-induced rise in the level of lncRNA-1 has a functional significance, we analyzed the impact of forced overexpression and knock-down of lncRNA-1 in neuronal cells. Interestingly, the level of lncRNA-1 expression correlated directly with cellular survival after stress. To determine the mechanism through which lncRNA-1 performs its pro-survival function in neurons, we purified lncRNA-1 along with its interacting proteins and identified the co-purified proteins using mass spectrometry. Interestingly, we identified FUS as a major interacting partner of lncRNA-1, suggesting that FUS may influence the biogenesis and/or function of lncRNA-1. To investigate this possibility further, we induced the expression of human ALS-associated FUS mutants in an HEK293 cell system and measured the effects on lncRNA-1 expression. Our preliminary results indicate that ALS mutants of FUS, but not wild type FUS, decrease the cellular level of lncRNA-1, suggesting that perturbation of the FUS-lncRNA-1 interaction or lncRNA-1 function could be relevant to neuronal vulnerability in one form of ALS. Further

study of the specific mechanism(s) by which FUS may affect lncRNA-1 function may provide novel insights into the impact of this or other lncRNAs in the pathogenesis of ALS.

Title: Non-cell autonomous fus/tls mediated toxicity in als.

Authors: *A. T. KIA, A. BOGUSH, D. TROTTI, P. PASINELLI
Jefferson Hosp. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease primarily characterized by degeneration and loss of motor neurons. Although most forms of ALS are sporadic (sALS), ~10% of patients suffer from a familial form (fALS). Mutations in several genes have been linked to fALS including fused in sarcoma (FUS), which accounts for ~5% of fALS cases. FUS is a DNA/RNA binding protein involved in multiple levels of gene expression including: DNA repair, RNA splicing, transcription, and transport of mRNA from the nucleus to distal destinations. While motor neurons are the primary target, ALS is a non-cell autonomous disease in which non-neuronal cells such as astrocytes and microglia contribute to motor neuron degeneration. In particular, in vitro systems demonstrated that astrocytes expressing SOD1 mutations are toxic to normal motor neurons when co-cultured. To determine whether FUS-expressing astrocytes are similarly toxic to motor neurons, we set up a co-culture system in which motor neurons are plated on astrocytes harboring mutant and wild-type FUS respectively. In our system, we determine motor neuron toxicity by measuring neurite outgrowth for each neuron as well as cumulative neurite sizes for each experimental population. To begin to address the mechanisms of FUS-astrocyte toxicity on motor neurons, we used conditioned media (CM) from wild-type or mutant FUS-expressing astrocytes to treat primary motor neurons. Our in vitro data indicate that similar to mutant SOD1 astrocytes, FUS expressing astrocytes contribute to motor neuron death.

Abstract: Background: Mutations in the Fused in Sarcoma (FUS) gene have been identified as a cause of FALS and classified as ALS-FUS. Most of the mutations cluster in the C-terminal part of the protein, which harbors a non-canonical nuclear localization signal. In the Belgian familial ALS patients we identified the R521H and the P525L mutations.
Objectives: We aimed to create small animal models to study the pathogenic mechanism of ALS-FUS.
Methods: Human FUS cDNA was incorporated into the *Drosophila* genome using site-directed integration. In zebrafish embryos transient overexpression of human FUS was obtained by injection of human FUS RNA and motor-axonal morphology investigated.
Results and Discussion: Overexpression of human FUS in the fly results in a larval and adult onset phenotype. Hatching problems have been observed in flies expressing human FUS during embryogenesis. Adult onset expression leads to severely reduced life span and motor performance defects. However, no differences were observed between wt and mutant FUS overexpressing flies.Transient expression of human FUS proteins in zebrafish embryos resulted in shortening and increased branching of motor axons. Also in this organism no significant difference was observed between wt and mutant FUS expressing zebrafish embryos.
To address the toxicity arising from human wt FUS, we deleted all functional domains from the wt protein and addressed toxicity in both animal models.
Conclusions: We have created two small animal models to study ALS-FUS pathogenesis. The *Drosophila* model will be used as a screening platform, to gain insight into the pathogenic mechanism and to identify disease-modifying genes. Potential hits will be validated

in the zebrafish model.

Abstract: Defects in neuromuscular junction (NMJ) stability are seen in animal models of spinal muscular atrophy (SMA) and amyotrophic lateral sclerosis (ALS) and these defects may play a role in motor neuron loss and muscle atrophy. In vivo examination of their physiological and biochemical properties is valuable, but examining NMJs in human cultures may provide additional insight into disease progression. Using SMA disease-specific induced pluripotent stem cells (iPSCs), we have generated cultures containing a mix of both neural and non-neural cell types. Upon further examination, we found HB9+/SMI32+ motor neurons along with Pax3+ and Pax7+ skeletal muscle progenitors and Myosin Heavy Chain (MHC)+ mature skeletal tissue. In order to optimize culture conditions for skeletal muscle, we dissociated and plated progenitor spheres in the presence of 2% B27, which significantly increased expression of skeletal muscle markers and produced more mature multi-nucleated and striated muscle cells. To date, two independent SMA patient lines and one control iPSC line have produced Pax3+, Pax7+ and MHC+ skeletal muscle cells. Further characterization showed upregulation of the appropriate skeletal muscle transcription factors Myf5, MyoD, and Myogenin in a temporal fashion. Pax3 expression has been seen in all lines; however, a significantly smaller proportion of cells express Pax7, which appears to be more indicative of MyoD, Myogenin, and MHC induction, and

ultimately skeletal muscle production. As such, further optimization is necessary for increasing Pax7 induction. Interestingly, recent reports have shown sustained neuregulin-1 (NRG-1) expression from neural crest cells maintains Pax7+ expression during embryonic development. Although we find HNK+ neural crest progenitors in our sphere cultures, they may be unable to significantly increase the expansion of Pax7+ cells. Therefore, we are incorporating exogenous NRG-1 along with additional factors into our culture conditions, such as insulin, EGF, and BSA, in order to improve efficiency of generating Pax7+ cells and subsequent sustainability of MHC+ skeletal muscle cells. Finally, in order to fully utilize this system, we are generating co-cultures of disease specific and control iPSCs to establish NMJs in vitro. Importantly, these co-cultures identify SMI32/ChAT+ motor neurons as well as synaptic markers synapsin, SV2, and fluorescent conjugated a-bungarotoxin. Establishing culture techniques that consistently generate patient specific iPSC derived skeletal muscle that can be used to form and maintain functional NMJs will be a powerful tool for studying a wide range of neuromuscular diseases.

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurological disease causing selective degeneration of upper and lower motor neurons. 90% of all cases are sporadic (sALS) and 10%

are familial (fALS) with identified mutations. One of the major genes mutated in fALS is superoxide dismutase 1 (SOD1). Multiple point mutations in SOD1 have been identified and many of these recapitulate human disease when overexpressed in rodents. In vitro models using transgenic neurons would enable mechanistic studies of motor neuron degeneration. However, ALS relevant phenotypes are difficult to reproduce in short term cell culture system, likely reflecting the late onset nature of the disease. One approach to address this problem is to screen for stressors that can selectively accelerate pathological changes linked to mutations causing ALS.

The aim of this project was to set up a cell-based assay suitable for high-throughput drug screening, aimed at identifying stressors acting in synergy with SOD1 mutations. Such an assay requires a large amount of motor neurons harvested or generated in a reproducible and time efficient manner. We therefore took advantage of a previously described protocol for differentiating embryonic stem cells (ES) into motor neurons (Wichterle et al. 2002). We derived a series of ES cell lines from blastocysts carrying one of two fluorescent reporters (eGFP or tagRFP) under the control of the motor neuron specific Hb9 promoter; together with either the wild type (WT) or ALS causing mutated form (G93A) of human SOD1. The screen for biological stressors provoking or accelerating cell autonomous phenotypes linked to mutations in SOD1 was performed on mixed cultures containing GFP positive SOD mutant and RFP expressing WT ES cell derived motor neurons. Survival of WT (RFP) and ALS (GFP) motor neurons was monitored using a live imaging platform and the analysis was carried out with unbiased automated image software. After validating the robustness of the assay, we used the setup to screen a library of 1300 small molecule compounds. The goal was to identify compounds preferentially reduce the survival of mutant motor neurons, thereby revealing potentially new mechanisms for selective motor neuron degeneration in ALS.

From this primary screen we identified 10 stressors that promoted selective loss of ALS motor neurons. We are currently validating these findings in secondary screens, mapping pathways regulated by the compounds, and testing whether the compounds also elicit preferential degeneration of human ALS motor neurons derived from patient induced pluripotent stem cells.

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease that primarily affects lower and upper motoneurons. In the G93A-SOD1 transgenic mouse model of ALS, one of the earliest detected differences from wild-type animals is enhanced expression of a persistent inward current (PIC) in spinal motoneurons (Kuo et al., J Physiol 563: 843-54, 2005; Quinlan et al., J Physiol 589: 2245-60, 2011). Using our recently developed in vitro adult spinal slice model (Carp et al, J Neurophysiol 100: 474-81, 2008), we studied spinal motoneuron intrinsic properties from a higher copy strain of G85R-YFP-SOD1 transgenic mice (Wang et al., PNAS 106: 1392-7, 2009) that becomes paralyzed by 5-6 months, in order to determine if enhanced PIC expression is a common feature of mutant SOD1 mice.
Four transgenic and four wild type mice (3 months) were anesthetized and perfused transcardially with cold low-Na+ artificial cerebrospinal fluid (aCSF). After dorsal laminectomy, the lumbosacral spinal cord was rapidly excised and transferred to a cold low-Na aCSF bath. The L3-S1 spinal cord was isolated, embedded in agar, and sliced transversely in 300-µm sections in cold low-Na aCSF with a vibrating microtome. Slices were incubated in 30% polyethylene glycol for 60 s and then in normal-Na aCSF at 34-36°C for one hr, and were maintained at 28-30°C.
We recorded intracellularly from 14 mutant and 13 wild-type motoneurons with action potentials (APs) ≥60 mV. During repetitive firing elicited by triangular current ramp injection, the differences between derecruitment and recruitment current and firing rate were more negative (i.e., lower current and firing rate at derecruitment than at recruitment) in mutant than in wild type motoneurons ($p=0.05$ and $p=0.01$ by t-test, respectively). There were no differences between mutant and wild type motoneurons in input resistance or current threshold (rheobase) for eliciting a single action potential.
The results suggest that G85R mice, like G93A mice, have enhanced PICs, despite differences between the two mutants in metallation and misfolding of the mutant SOD1 protein. Thus, they support the hypothesis (Quinlan, Integr Comp Biol 51: 913-25, 2011) that enhanced PIC

expression contributes to metabolic stress, and thereby increases motoneuron vulnerability in SOD1-mutant mice.

Title: Futher analyses of the role of astrocytes on motor neuron death in an *in vitro* model of Amyotrophic Lateral Sclerosis

Authors: *J. M. SCORISA, T. DUOBLES, G. P. OLIVEIRA, J. R. MAXIMINO, G. CHADI
FMUSP, Sao Paulo, Brazil

Abstract: The Amyotrophic Lateral Sclerosis (ALS) is a progressive neurodegenerative disorder characterized by a selective death of motor neurons. The transgenic mouse expressing human superoxide dismutase 1 (SOD1) gene with a G93A mutation (SOD1G93A) is the most accepted experimental model to study disease mechanisms. Recent studies indicate that astrocytes contribute to the ALS disease, however the molecular mechanisms are not yet established. Moreover, in vitro models describing toxic influence of astrocytes to motor neurons are based upon astrocytes collected from newborn mouse and also post morten material from spinal cord of ALS patients. Here we investigated the role of astrocyte in promoting motor neuron toxicity at pre-symptomatic phase of ALS.
Astrocyte cell cultures were obtained from spinal cord of post natal day 1 (P1) and 60 (P60) SOD1G93A (TG) and wild type (WT) mice. Motor neuron cell culture was performed from spinal cord of P1 neonatal of both genotypes. Firstly, the TG and WT motor neurons were treated with conditionated medium of TG and WT astrocyte cultures (n=3wells) and neuronal medium was used as a control. Secondly, TG and WT astrocytes were co-cultured with TG and WT motor neurons. Neurite length of motor neurons was measured by a stereological method at the first and fifth days of culture and neuronal death was quantified using a Flouro JadeC marker. Conditioned medium experiment demonstrated that TG astrocytes derived from P1 and P60 led

to a less neurite growth of TG cultured spinal cord motor neurons [124% (P1) and 90.5% (P60, $p<0.05$)] compared to WT [188% (P1) and 125% (P60)]. Co-cultured experiments have shown a higher neuronal death of TG cultured spinal cord motor neurons [50.6% (P1, $p<0.05$) and 53.43% (P60, $p<0.05$) compared to WT [10.9%(P1) and 20.4% (P60) mice. The results also showed that the above described events were more pronounced considering the astrocyte cultures of P60 TG than neonatal TG ($p<0.05$)
In conclusion, the astroglial toxicity to motor neurons in the ALS seems to be more pronounced at the period close to pre-symptomatic phase thus influencing the disease onset.

Title: Guanabenz reduces proteasome dysfunction induced by tunicamycin in primary cell lines from mouse models of als

Authors: *J. DE ZUTTER, Y. JIANG, P. QUINGGONG, M. WANG, G. LI, J. LINCECUM, F. VIEIRA, A. GILL, S. PERRIN
ALS Therapy Develop. Inst., CAMBRIDGE, MA

Abstract: 2,6-dichlorobenzylidenaminoguanidine (Guanabenz, GA), an a2 adrenergic receptor agonist, is a well studied antihypertensive drug with more recently identified neuroprotective properties. Mechanisms proposed for GA's protective effect include, binding to the ribosome to inhibit it's protein folding activity and binding to and inhibiting a phosphatase, PPP1R15A/GADD34, which mediates translation initiation factor 2 (eIF2a) -dependent protein translation. Defects in protein folding and proteasomal function have been hypothesized to cause cell death, dysfunction and symptoms in amyotrophic lateral sclerosis (ALS). To establish a model of neurodegeneration, we treated primary cells from wild type and ALS mouse models with the proteasome dysfunction inducer, tunicamycin. Tunicamycin induced a dose dependent reduction in cell viability as measured by WST-1 assay. Pre-treating cells with 10uM guanabenz blocked 25% of the cell death induced by 0.1-0.3 uM tunicamycin as measured by WST-1 assay. Tunicamycin treatment also caused robust changes in unfolded protein response (UPR) and apoptosis mediator’s gene expression as determined by RT-qPCR assay. Guanabenz

concentrations of 10-30 uM caused a 25% reduction in UPR genes CHOP and Bip and an approximately 25% increase in Bcl2 gene expression compared to basal levels. Tunicamycin (0.1-0.3 uM) -induced changes in gene expression were altered to the same extent by 10 uM guanabenz as they were in response to GA treatment alone. We conclude guanabenz may exert a protective effect by mediating cellular response to defects in proteasome function and the unfolded protein response. The current studies inform us of dosing parameters to be used for in vivo mouse study design. These data also suggest that guanabenz may have a beneficial effect in the G93A SOD1 mouse model for ALS which is characterized by defects in proteasomal function.

Title: The activity of anti-aggregant and pro-degradative molecules varies with the polyQ size in cell models of spinal and bulbar muscular atrophy (SBMA)

Authors: *A. POLETTI, E. GIORGETTI, P. RUSMINI, V. CRIPPA, A. BONCORAGLIO, R. CRISTOFANI, E. BOLZONI
Dept. di Scienze Farmacologiche e Biomolecolari, Ctr. of Excellence On Neurodegenerative Diseases-Università Degli Studi Di Milano, Milano, Italy

Abstract: The CAG/PolyQ-related diseases comprise nine different neurodegenerative disorders in which neuronal death is triggered by a mutant protein with an elongated polyglutamine stretch (polyQ). To cause disease, the polyQ size has to reach a specific threshold (tipically 35-40 Gln), but disease severity increases proportionally to polyQ size. Shorter (Q-35-Q60) polyQs associate with higher age-of-onset, milder symptoms and slower progression rate than longer polyQs (Q61-Q120 and over). Several factors are capable to counteract aggregation and induce degradation of mutant polyQ proteins, but their power against polyQ of different size might differ. We thus studied the effects of some compounds/proteins on a CAG/polyQ disease, the SpinoBulbar Muscular Atrophy (SBMA), caused by the polyQ of the androgen receptor (AR). SBMA is a motor neuronal disease and it is particularly useful since mutant AR neurotoxicity can be triggered by its ligand testosterone. We utilized AR with different polyQ length (non-

pathological Q0, Q10, Q22, or pathological Q48, Q112) expressed in immortalized motor neuronal (NSC34) cells. We also used a doxycycline-inducible PC12 cells expressing AR.Q10 or AR.Q112 (D. Merry, TJU, Philadelphia). Typically, after testosterone treatment, AR.Q46 aggregates in cytoplasm both in NSC34 and PC12 cells, while AR.Q112 aggregates in nuclei, but only when stably expressed in PC12 cells. We found that a small heat shock protein, HSPB8, prevents mutant AR.Q48 aggregation. HSPB8 acts by inducing AR.Q48 degradation via the autophagic pathway, without interfering with the proteasome. Interestingly, HSPB8 was much less efficient with the AR.Q112 (both transiently or stably expressed in PC12 or NSC34 cells). We also utilized the disaccharide trehalose and the artificial chaperone cyclodextrin (CD, a water soluble, non-toxic, cyclic oligosaccharide used as vehicle for drug delivery). Both trehalose and CD were active on AR.Q48, but less efficient on AR.Q112 aggregation and clearance. In fact, both compounds efficiently inhibited AR.Q46 aggregation rate (evaluated in ICC and filter retardation assays) and decreased protein levels (evaluated in western blot). Therefore, our data indicate that both molecular and chemical approaches can counteract aggregation and facilitate clearance of ARpolyQ with shorter pathological repeats, but showed different pro-degradative and/or anti-aggregation power on ARs with different polyQ length. Since the longest repeats described in SBMA patients are of approximately 70Qs, these aspects may be relevant in the choice of the models on which one should test compounds to be used in future therapeutical trials.

Abstract: SBMA (Spinal and bulbar muscular atrophy) is a motor neuron disease caused by the expansion of the CAG triplet repeats within the gene encoding the AR (androgen receptor). We performed the gene expression analysis for the spinal cord of SBMA model mice with DNA microarray, and identified the disease related gene CGRP1 (calcitonin gene-related peptide alpha). CGRP1 is a multifunctional neuropeptide and is thought to react with autocrine-paracrine mode in spinal motor neurons, but the pathological function is not well known. Therefore, we made the biochemical and pathological analysis (western blotting, ELISA, RT-PCR, cell viability assay, cell cytotoxic assay, immunohistochemistry etc.) of CGRP1 for SBMA model cells (SH-SY5Y stably expressing mutant AR) and mice (mutant AR transgenic mice), and searched for the therapeutic strategy. CGRP1 expressed intensively in the motor neuron of SBMA model mice, and was also detected in the post mortem spinal cord of the patients. In neuronal cell, the over-expression of CGRP1 reacted toxically via the activation of the c-Jun N-terminal kinase (JNK) pathway, and the genetical / pharmacological suppression of CGRP1 (siRNA / CGRP1 antagonist, CGRP8-37) or JNK inhibitor, SP-600125 rescued from the neurotoxicity. In a mouse model of SBMA, the CGRP1 expression level in the spinal cord was attenuated by the castration, and the depletion of CGRP1 ameliorated the phenotypes (survival rate, body weight, rotarod task, and grip) and deactivated the JNK pathway. We searched CGRP1 suppressor for SBMA therapy, and naratriptan, a 5HT1B/1D agonist was chosen for the long lasting reactivity and the blood brain barrier permeability among the three agonists (naratriptan, sumatriptan, and rizatriptan). Naratriptan suppressed CGRP1 expression via the induction of MKP1 (mitogen-activated protein kinase phosphatase 1), and attenuated JNK activity. The 5HT1 receptor blocker, methiothepin offset the effect of naratriptan in cellular SBMA models. Naratriptan mitigated the pathogenic AR-mediated neuronal damage in cellular and mouse SBMA models. CGRP1 is a new therapeutic target for SBMA and the pharmacological activation of the 5HT1B/1D receptor is a novel therapeutic strategy for this disease.

Inst. on Aging, NIH, Bethesda, MD

Abstract: The C9ORF72 hexanucleotide repeat expansion has been identified in ~30% of familial and ~4-10% of sporadic ALS cases and is therefore the most common genetic abnormality associated with ALS to date. Repeat expansions in non-protein coding regions are the known cause of other neuromuscular disorders (e.g., DM1/2, FXTAS) and pathogenicity is thought to arise from aberrant binding of trans acting factors to the cis repetitive elements. This is best studied in DM1 where MBNL1 is sequestered by the 'CTG' expansion in the DMPK pre-mRNA. Therefore, antisense oligonucleotide (ASO) and RNAi (siRNA) strategies designed to block binding to the cis elements may have therapeutic potential in these disorders. To test this possibility in the context of C9orf72 ALS, we designed siRNA and ASO methodologies to target the C9ORF72 transcript and repeat expansion, and have demonstrated knockdown the C9ORF72 gene in patient-derived cell lines. Furthermore, utilizing our transcriptome profiling generated from C9ORF72 ALS patient fibroblasts, iPS derived CNS cells and validated with human autopsy tissue, we show that ASO/RNAi treatment can normalize specific genes which are aberrantly expressed in cell lines that contain the 'GGGGCC' expanded repeat. These approaches will allow us to effectively develop 1) antisense mediated therapeutic approaches to ALS and 2) relevant pharmacodynamic readouts for antisense efficacy.

Title: RBM45 pathology in sporadic and C9ORF72-linked amyotrophic lateral sclerosis

Authors: *M. A. COLLINS[1], T. KOVALIK[2], D. RIASCOS[2], R. BOWSER[2]
[1]Neurosci., Univ. of Pittsburgh, Phoenix, AZ; [2]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: RNA binding protein pathology is a pathological hallmark of amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD). Using liquid chromatography tandem mass spectrometry (LC/MS-MS), we recently identified the RNA binding protein RBM45 as a putative ALS biomarker. Immunohistochemistry revealed the presence of RBM45-positive inclusions, similar in appearance to those containing TDP-43, in ALS patients. These could be detected in ALS cases with the c9ORF72 hexanucleotide repeat expansion. Recent evidence suggests that c9ORF72-linked ALS has a distinct pathological profile. This study was conducted to further describe the RBM45 pathology in the central nervous system of sporadic and c9ORF72-linked ALS cases and to assess the normal distribution, expression, and subcellular localization of the protein. ALS, C9ORF72-linked ALS, FTLD, and age-matched control patient tissues were used. Regions examined included spinal cord, hippocampus, cerebellum, and frontal cortex. RBM45 expression was evaluated by immunohistochemistry and immunoblot. Immunofluorescence was used to examine the colocalization of RBM45 with TDP-43, stress granule markers, ubiquitin, p62, and SC35. Immunoblot results demonstrated modestly increased levels of RBM45 in the CSF of ALS patients, consistent with our LC-MS/MS data. By immunohistochemistry we detected RBM45 inclusions in spinal cord motor neurons and glia of sporadic and c9ORF72-linked ALS cases. The number of surviving motor neurons and percentage of these harboring RBM45 inclusions was higher in c9ORF72-linked ALS than in sporadic ALS. Cytoplasmic RBM45 inclusions could be seen in the dentate gyrus of FTLD patients and, more rarely, sporadic ALS cases. Inclusions were not seen in control cases. RBM45 inclusions were frequently positive for TDP-43, ubiquitin, and stress granule markers. RBM45 also exhibited a speckled nuclear staining pattern that was negative for the nuclear speckle marker SC35. In this study we have further characterized RBM45 pathology in ALS and have added to existing evidence suggesting that sporadic ALS and c9ORF72-linked ALS differ pathologically. Nevertheless, the colocalization of RBM45 inclusions with TDP-43 and stress

granule markers suggests common mechanisms of inclusion formation. The speckled nuclear staining pattern observed for RBM45 distinguishes it from TDP-43. This pattern was also separate from SC35-positive nuclear speckles, implying that RBM45 is a component of a distinct subnuclear structure. Ongoing studies will determine RBM45's role in RNA metabolism, stress response, and how these processes might contribute to neurodegeneration.

Title: Decreased expression of BTBD10 in ALS motor neurons may contribute to the ALS pathogenesis

Authors: *M. NAWA, M. MATSUOKA
Pharmacol., Tokyo Med. Univ., Tokyo, Japan

Abstract: BTBD10, an Akt interactor, increases phospho-Akt levels by decreasing the protein phosphatase 2A-mediated dephosphorylation of Akt. In this study, we found that the level of BTBD10 expression is decreased in spinal cord motor neurons from the patients of sporadic ALS and transgenic mice overexpressing G93A-SOD1. We further investigated whether the reduction of BTBD10 is linked to the ALS pathogenesis. The overexpression of BTBD10 suppressed motor neuron death that was induced by a familial ALS-inked superoxide dismutase (SOD) 1 mutant, G93A-SOD1 *in vitro*. Reciprocally, the siRNA-mediated reduction of BTBD10 expression led to the death of cultured motor neuron. In *Caenorhabditis elegans*, the disruption of the *btbd-10* gene caused loss of neurons, including both motor and touch-receptor neurons, and a locomotion defect. Interestingly, the low-level expression of fused in sarcoma (FUS), an ALS-linked protein, downregulated the level of BTBD10 expression and simultaneously induced neuronal cell death. Our ongoing study is aimed at addressing the mechanism underlying the FUS-induced neuronal cell death from a standpoint of the BTBD10 involvement.

Title: Mutated SOD1 causes mitochondrial damage in astrocytes

Authors: *N. NANICHE, W. TAN, D. TROTTI, P. PASINELLI
Thomas Jefferson Univ., Philadelphia, PA

Abstract: Amyotrophic lateral sclerosis (ALS) is a slowly progressing, ultimately fatal neurodegenerative disease affecting mainly motor neurons in the motor cortex, brainstem and spinal cord. ~ 20% of all inherited cases of ALS (fALS) are caused by mutations in the gene encoding for superoxide dismutase 1 (SOD1), which lead to a gain of toxic function(s) of the protein. Although motor neurons are the predominant cells that die during ALS, glial cells are also known to contribute pathologically to the progression of disease. A number of studies have shown the importance of knocking out mutSOD1 from glia towards ameliorating disease. While many of these studies looked at the toxic effects that astrocytes have on motor neurons, fewer have looked at the effect that mutSOD1 has on astrocytes themselves, in particular on astrocyte mitochondria. While a predominately cytoplasmic protein, a small portion of SOD1 has been shown to localize to the mitochondria, where when mutated the protein can cause mitochondrial damage and toxicity. In this study, we analyze the effects of mutSOD1 specifically on astrocyte mitochondria. Using wild-type (WT) or G93A-mutated SOD1 plasmid in an adeno-virus (Adv-SOD1), we infected primary non-transgenic spinal cord astrocytes with Adv-SOD1 over a time-course to look for mitochondrial morphological and bioenergetic changes. We found that over an eight-day time course, there was little to no effect of WT Adv-SOD1 on astrocyte mitochondria in terms of morphology, bioenergetics or protein level changes. However, there were dramatic changes seen in G93A Adv-SOD1 treated astrocytes. Mutated SOD1 aggregates were seen in infected astrocytes that led to aggregation of mitochondria. Shifts in mitochondrial membrane potential were seen throughout the eight-day treatment, and mitochondrial protein levels were decreased over time in these astrocytes. However, astrocytes were still alive even with these mitochondrial abnormalities after G93A Adv-SOD1 treatment. Our data suggest that mutSOD1 causes substantial mitochondrial alterations to astrocytes, without causing astrocyte death or

toxicity in the same rapid fashion as it does in motor neurons. Studies are underway to determine the cellular differences in response to mitochondrial damage between motor neurons and astrocytes.

Title: Pathogenic role of astrocyte exocytosis in ALS

Authors: S. NG, N. DIAZ, *H. HIGASHIMORI, L. MOREL, P. HAYDON, Y. YANG
Neurosci., Tufts Univ., Boston, MA

Abstract: The recognition of the active roles of glial cells in the physiology of mammalian central nervous system (CNS) is significantly changing the view how neurodegeneration occurs and progresses. In ALS, many lines of evidence have clearly suggested that astrocytes are involved in pathogenesis and can significantly modulate disease phenotype. Recent in vitro studies found that SOD1G93A astrocytes can selectively induce motor neuron cell death through secreted toxic factors. This implicates a primary and direct role of astrocyte gain-of-toxicity in motor neuron death. However, the exact mechanisms/pathways that underlie astrocyte mediated toxicity in ALS remain poorly understood. Exocytosis represents one of the major pathways for the secretion of active substances from astrocytes, which is SNARE-dependent and requires membrane fusion between the vesicle membrane and plasma membrane. In this project, we investigated the effect of astrocyte exocytosis inhibition on the disease phenotypes in SOD1G93A mice in vivo. Selective inhibition of the exocytosis pathway in astrocytes has been previously achieved by expressing the cytosolic portion of the SNARE protein synaptobrevin 2 in cultured astrocytes and in doxycycline (Dox) regulated Tet on/off transgenic mice (GFAP-tTA/TetO-SNARE mice). We have bred these mice with SOD1G93A mice to generate triple SOD1G93A+SNARE+tTA+ transgenic mice. Dox was supplemented into the food during breeding and was removed once the mice were weaned (P21). Induction of SNARE was confirmed by the co-expression of the eGFP reporter in the spinal cord. Disease phenotypes, including forelimb and hindlimb grip strength, weight loss, and survival, were closely examined weekly in these mice starting from P60. A significant delay in disease onset (defined by 10% loss of forelimb grip strength) was found in SOD1G93A+SNARE+tTA+ mice (α=104, N=8)

compared to that of littermates SOD1G93A+ mice (α=94, N=13). Similarly, the late disease onset (defined by 10% weight loss) in SOD1G93A+SNARE+tTA+ mice is also significantly delayed (α=131, N=8) compared to that in SOD1G93A+ mice (α=119, N=13). However, the disease duration time (from the onset to the end-stage) between SOD1G93A+SNARE+tTA+ (α= 41, N=8) and SOD1G93A+ (α=47, N=13) mice is not significantly different. In fact, SOD1G93A+SNARE+tTA+ mice tend to have shorter disease progression than that in SOD1G93A+ mice (though not statistically significant). We are currently investigating the effects of exocytosis-inhibited SOD1G93A astrocytes on motor neuron cell survival using in vitro co-culture system.

Title: Abnormal store-operated calcium entry and ER calcium release in mutant SOD1 astrocytes

Authors: *H. KAWAMATA[1], G. MANFREDI[2]
[1]Weill Med. Col. of Cornell Univ., NEW YORK, NY; [2]Weill Med. College, Cornell Univ., New York, NY

Abstract: Calcium release from the endoplasmic reticulum (ER) stores is the main source of calcium signaling in astrocytes. To maximize signaling effects, cytosolic calcium concentrations are tightly controlled by the interactions of multiple calcium regulating systems, including mitochondria, ER, and plasma membrane. After ER calcium release, plasma membrane calcium channels are activated to replenish the calcium that has been extruded from the cell, a mechanism defined as store-operated calcium entry (SOCE).

We investigated the mechanisms of ER release following purinergic receptor stimulation and SOCE, in cultured adult spinal cord astrocytes from mutant SOD1 transgenic mice. With ATP stimulation of the IP3 receptor, ER calcium release in mutant astrocytes was enhanced as compared to non-transgenic cells. Depleting ER calcium with the SERCA inhibitor caused higher ER calcium release from mutant astrocytes, suggesting increased ER calcium stores. The calcium clearance through the plasma membrane and mitochondria did not differ between mutant and control astrocytes. In addition, the increased ER calcium release did not correlate with changes in ER volume or decreased levels of the ER calcium-binding protein calreticulin. Mutant astrocytes had a significantly increase in the influx of calcium by SOCE, which could explain the increased ER calcium content in mutant cells. We further investigated the sensitivity to SOCE inhibitors, and found that mutant astrocytes were partially insensitive to STIM1-ORA1 inhibition.

STIM1 glutathionylation results in a constitutively active protein, which opens ORA1 calcium channels on the plasma membrane. This posttranslational modification renders STIM1 insensitive to ER calcium levels and may result in chronic increase of ER calcium filling. To test the hypothesis that glutathionylation of STIM1 results in increased calcium entry, we treated mutant SOD1 cells with the antioxidant BHA, which completely normalized the SOCE response. Vice versa, treatment with BSO, which depletes GSH levels and causes oxidative stress, resulted in increased calcium entry in control cells

These findings suggest that mutant SOD1 causes increased ER calcium levels by promoting oxidative stress and glutathionylation of STIM1 in astrocytes. This could provide a mechanistic explanation for the abnormal calcium dynamics in mutant SOD1 astrocytes. Although astrocytes are spared in mutant SOD1 associated familial amytrophic lateral sclerosis, abnormal calcium properties in the astrocytes may be involved in the non-cell autonomous toxicity to motor neurons by altering the tripartite synaptic milieu.

Title: Mutation in ubiquilin4 in ALS patient affects the ubiquitin proteosome system and Autophagy *in vitro*

Authors: K. AJROUD, 1[1], J. YAN, 2[1], F. FECTO, 3[1], Y. SHI, 4[1], N. SIDDIQUE, 5[1], J.-G. ZHENG, 6[1], *E. MUGNAINI[2], H.-X. DENG, 8[1], T. SIDDIQUE, 9[1]
[1]Neurol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Inst. Neurosci., Northwestern Univ., CHICAGO, IL

Abstract: Growing evidence supports the notion that impairment of the proteosome and autophagy are associated with the formation of protein aggregates and neurodegeneration including ALS. We recently reported mutations in Ubiquilin2, member of the Ubiquilin family affecting both the Ubiquitin Proteosome System (UPS) and Autophagy in vitro. We have now identified a mutation in Ubiquilin4 gene in a familial ALS patient. Ubiquilin4 is a member of the Ubiquilin family and also plays a role in the regulation of proteasomal protein degradation. The aim of the current study is to test whether the identified mutation in Ubiquilin4 affects the UPS and the Autophagy in vitro. We performed genomic DNA sequencing of familial ALS cases as well as controls and generated a cell line model (Neuro2A cells, N2A) expressing Ubiquilin4 to evaluate the expression of the Ubiquilin4 wild type and mutant and conducted colocalisation with autophagosome markers and ALS linked proteins using Confocal microscopy and Flow cytometry. We identified a mutation in the exon 3 of Ubiquilin4 gene that was absent from controls. We also found four single nucleotide polymorphisms (SNP) that were present in the controls. N2A cells transiently transfected with Ubiquilin4 tagged to mCherry showed punctuate structures in both wild type and mutant. Flow cytometry reveled a significant accumulation of LC3-GFP which corresponds to an inhibition of autophagic activity in mutant Ubiquilin4 transfected cells. Consistent with this, we observed that both wt and mutant Ubiquilin4 co-localize with LC3, p62 and subsequently Ubiquilin2. However we found a significant decrease in the Rab7-GFP accumulation in the mutant Ubiquilin4 transfected cells which may indicate impairment at the autophagosome late endosome formation and exacerbating the decrease in the autophagy activity. These data suggest that mutant Ubiquilin4-mediated autophagy impairment may be responsible for ALS pathogenesis. Such a mechanism could participate in the accumulation of the aggregation-prone proteins in ALS, and impair essential regulatory functions of autophagy and the UPS. Hence, autophagy-related proteins, like Ubiquilin4, represent an attractive target for designing rational therapeutics in ALS.

Title: Homeostatic regulation of excitability in SOD1 mouse motoneurons

Authors: M. MANUEL[1,2], N. DELESTREE[1], S. M. ELBASIOUNY[2], C. IGLESIAS[1], C. J. HECKMAN[2], *D. ZYTNICKI[1]
[1]Lab. de Neurophysique et Physiologie, CNRS, Univ. Paris Descartes, Paris, France; [2]Dept. of Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Excitotoxicity has been proposed as a mechanism leading to the selective death of MNs in Amyotrophic Lateral Sclerosis (ALS). It is indeed known that increase excitation and hyperexcitability can cause the death of motoneurons (MNs). However, it has yet to be demonstrated that spinal MNs exhibit changes in their excitability in the days preceding their degeneration. The aim of this work is therefore to test this hypothesis.
To do so, we recorded the intrinsic properties of MNs in SOD1 mice at an age (P50) just preceding the first denervations of motor units in two regions of the spinal cord affected by the disease: the sacro-caudal cord and the lumbar cord.
At odds with the excitotoxicity hypothesis we observed that SOD1 MNs did not exhibit signs of hyperexcitability in either region of the spinal cord. In particular, we observed that the input conductance of SOD1 MNs was significantly increased compared to controls. In the lumbar cord, the input conductance of MNs was 0.31±0.13µS (N=25) in WT mice, whereas it was 0.46±0.18µS (N=25; $p<0.005$) in mutant animals. Despite this increase of conductance, the excitability of the motoneurons was preserved. Neither the onset current for repetitive firing (4.7±3.1nA; N=10 vs. 5.9±3.0nA; N=10), nor the gain of the current-frequency relationship (11±2Hz/nA; N=6 vs. 16±7Hz/nA; N=8) were statistically different between SOD1 and WT mice.
Our new results show that MN conductance continues to increase as the SOD1 animal matures, pushing some cells well above the normal limits. Yet, net excitability continues to remain normal, clearly requiring an increase in voltage sensitive currents as a compensatory mechanism. Thus MNs in ALS do not become hyperexcitable but instead undergo a notably successful

homeostatic regulation for excitability. Although initially this homeostasis helps the animal maintain normal motor output, the progressive increases in cell size and density of membrane channels could lead to their degeneration.

Title: Characterization of the motor neuron death processes in two models of excitotoxicity in the rat spinal cord *in vivo*.

Authors: *U. N. RAMIREZ-JARQUIN, R. TAPIA
Inst. De Fisiología Celular, Univ. Nacional Autónoma De México, Mexico City, Mexico

Abstract: Among the multiple factors involved in motor neuron (MN) degeneration in amyotrophic lateral sclerosis (ALS), glutamate-mediated excitotoxicity seems to be of relevance. Based on the overactivation of AMPA type glutamatergic receptors, we developed two models of MN degeneration in the rat spinal cord, one by AMPA perfusion during 25 min using the microdialysis technique (acute model, J. Neurochem. 89:988, 2004.), and the other by the continuous infusion of AMPA with osmotic minipumps (chronic model, J. Neuropathol. Exp. Neurol. 66:913, 2007). Both models induce MN loss and motor deficits similar to ALS, the acute one during the 12 initial hours after AMPA perfusion and the chronic one during 2-5 days after the implant of minipump. In order to know the process of MN death, we studied comparatively in the two models the time course of the morphological and biochemical changes in the tissue, by means of electronic and confocal microscopy. In the acute model, MN degeneration starts 3-4 h after the AMPA perfusion and is characterized by swelling and rupture of cytoplasmic, nuclear and mitochondrial membranes, which progress until total disruption of cell structure at about 12 h. At 24 h macrophage-like cells around remnant cell debris were observed. In this model no cleaved caspase-3 or DNA fragmentation (TUNEL) were detected at any time. In the chronic model, MN loss and motor deficit occur gradually, starting in the ipsilateral side the second day

after the beginning of AMPA infusion and progressing to the contralateral ventral horn. We identified four degenerative stages during the progress of MN degeneration, as follows: stage 1, vacuolization of the cytoplasm (days 1-2); stage 2, swelling of endoplasmic reticulum and mitochondria (days 2-4); stage 3, formation of “empty pools” (large intracellular zones without cellular components, probably resulting from the fusion of vacuoles) (days 3-5); stage 4, rupture of the cytoplasmic membrane. Macrophage-like cells also appeared from day 2. Cleaved caspase-3 and TUNEL were detected immunohistochemically in MNs, but only in stages 2-3. We conclude that necrosis is the predominant MN death process in the acute model, whereas in the chronic model degeneration starts by apoptosis but a necrotic process develops afterwards. These findings are relevant for the understanding of MN death mechanisms and consequently for the design of pharmacological strategies directed to the treatment or prevention of ALS.

Univ. of Genoa, Genoa, Italy

Abstract: Amyotrophic lateral sclerosis (ALS) is a late-onset fatal neurodegenerative disease characterized by muscle wasting, weakness and spasticity, reflecting a degeneration of upper and lower motor-neurons (MNs). The cause of ALS and the mechanisms of neuronal death are still largely obscure, thus impairing the establishment of efficacious therapies. Glutamate(Glu)-mediated excitotoxicity plays a major role in the degeneration of MNs in ALS and reduced

astrocytary glutamate transport in spinal cord, which in turn increases the synaptic availability of the amino acid neurotransmitter, was suggested as a cause. On the basis of our studies, we alternatively proposed that abnormal release of Glu may well represent a possible source of excessive glutamate transmission. In this line, we recently demonstrates the existence of mGlu1 and mGlu5 Glu-releasing autoreceptors in spinal cord nerve terminals, whose activation produces higher Glu release in SOD1/G93A mice, a widely used animal model of human ALS, than in controls.
In the present work we generated mice carring half expression of mGlu1 receptors in the SOD1/G93A background, by crossing the SOD1/G93A mutant mouse with Grm1+/crv4 mouse, which lacks mGluR1 because of a spontaneous recessive mutation, thus providing a genetic tool to evaluate the role of mGlu1 receptors in ALS. Double mutants were analysed for survival and motor abilities, as well as for biochemical and histological parameters linked to the disease progression. Double mutants showed prolonged survival probability with respect to single mutant SOD1/G93A mice. Accordingly, slower disease progression and improved motor performances were observed. Histological studies showed MN preservation in spinal cord, reduced mithocondrial damage and axonal degeneration, decreased astrocyte and microglia activation in double mutant mice. Moreover, the mGluR1 deletion turned around the up-regulation of metallothioneines, glutathione S-transferase and iNOS mRNA expression present in SOD1/G93A mice. This study demonstrates that mGlu1 receptor deletion has a significant impact on survival and motor performances in mice with experimental ALS, thus providing the rationale for the selective block of these receptors as a novel pharmacological approach in the treatment of this disease.

Title: Characterization of a unique SOD1 mouse model for Amyotrophic lateral sclerosis

Authors: R. SACCON[1], P. JOYCE[2], P. FRATTA[1], L. GREENSMITH[3], *P. M. NOLAN[2], A. ACEVEDO[2], E. FISHER[1]

[1]Dept. of Neurodegenerative diseases, Inst. of Neurol. Univ. Col. London, London, United Kingdom; [2]MRC Harwell, Oxfordshire, United Kingdom; [3]Dept. of Motor Neurosci. and Movement Disorders, Sobell University, Univ. Col. London, London, United Kingdom

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease characterized by the loss of upper and lower motor neurons (MNs). In patients, the disease leads to paralysis and is fatal within 2-5 years of onset, generally due to respiratory failure. ALS is mostly sporadic but approximately 10% of cases are familial (FALS). Mutations in the Cu/Zn superoxide dismutase type 1 (*SOD1*) gene are known to cause FALS. Several SOD1 transgenic mice modelling ALS provide evidence of a toxic gain of function mechanism. While the toxic gain of function has been proven to be causative of the disease, a reduction of SOD1 function is not sufficient to provoke loss of MNs, but it does make MNs more susceptible to damage. SOD1 dismutase activity has been measured in a variety of human ALS patients carrying different mutations in *SOD1*. In the great majority of cases, SOD1 activity is reported to be reduced to ~50%. This activity reduction is not reproduced in SOD1 transgenic mouse models, as they express mutant SOD1 in addition to the normal mouse alleles. To better represent the human disease, a new SOD1 mouse model has been generated using MRC Harwell's N-ethyl-N-nitrosourea (ENU) mutagenesis program. This new mouse strain carries a single point mutation in the mouse endogenous *Sod1* gene (D83G), a mutation previously found in a familial ALS kindred. As this new mouse model carries the D83G mutation in the mouse *Sod1* gene, mutant SOD1 will be expressed at endogenous levels, making it biochemically more relevant to the human condition. We have measured SOD1 activity in brain extracts from these mice and found that heterozygotes ($Sod1^{D83G/+}$) have a ~50% reduction whereas homozygotes ($Sod1^{D83G/D83G}$) are dismutase inactive. Data from our group shows that homozygous mice ($Sod1^{D83G/D83G}$) display weakness and motor neuron degeneration which models aspects of human ALS. In order to further characterize this model and gain some insights on the pathological mechanisms of ALS, we are presenting an immunohistochemical, biochemical and molecular analysis of these mice.

Abstract: Amyotrophic lateral sclerosis (ALS) is a late-onset fatal neurodegenerative disease characterized by muscle wasting, weakness and spasticity, reflecting a degeneration of upper and lower motor-neurons (MNs). The cause of ALS and the mechanisms of neuronal death are still largely obscure, thus impairing the establishment of efficacious therapies. Glutamate-mediated excitotoxicity plays a major role in ALS and reduced astrocytic glutamate transport was suggested as a cause. Based on previous work we have proposed that abnormal release may represent another source of excessive glutamate. In this line, here we studied the modulation of glutamate release in ALS by Group I metabotropic glutamate (mGlu) receptors, that comprise mGlu1 and mGlu5 members. Synaptosomes from the lumbar spinal cord of SOD1/G93A mice, a widely used murine model for human ALS, and controls were used in release, confocal or electron microscopy and Western blot experiments. Concentrations of the mGlu1/5 receptor agonist 3,5-DHPG >0.3 μM stimulated the release of [3H]D-aspartate, used to label the releasing pools of glutamate, both in control and SOD1/G93A mice. At variance, ≤0.3 μM 3,5-DHPG increased [3H]D-aspartate release in SOD1/G93A mice only. Experiments with selective antagonists indicated the involvement of both mGlu1 and mGlu5 receptors, mGlu5 being preferentially involved in the high potency effects of 3,5-DHPG. High 3,5-DHPG concentrations increased IP3 formation in both mouse strains, whereas low 3,5-DHPG did it in SOD1/G93A

mice only. Release experiments confirmed that 3,5-DHPG elicited [3H]D-aspartate exocytosis involving intra-terminal Ca2+ release through IP3-sensitive channels. Confocal microscopy indicated the co-existence of both receptors presynaptically in the same glutamatergic nerve terminal in SOD1/G93A mice. To conclude, activation of mGlu1/5 receptors produced abnormal glutamate release in SOD1/G93A mice, suggesting that these receptors are implicated in ALS and that selective antagonists may be predicted for new therapeutic approaches.

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a devastating neurological disease that leads to progressive death of motoneurons in the spinal cord and the motor cortex, with an average survival time of only 1-5 years after diagnosis. Mutations in the gene for superoxide dismutase 1 (SOD1) have been identified as the major cause of familial ALS, and mouse models based on the overexpression of mutant human SOD1 have proofed to be valuable models for the disease. Although a lot of effort has been made, the underlying pathomechanisms leading to the specific death of motoneurons still have to be elucidated. Occurrence of protein aggregates is a major hallmark in human ALS and can be observed in mutant SOD1 (SOD1-mt) transgenic mice. Whether protein aggregates play a causal role in the disease is still a matter of debate and several

additional pathomechanisms have been proposed. As one hypothesis, glutamate excitotoxicity, leading to missregulation of intracellular calcium levels and subsequent apoptosis, is discussed. Visinin-like protein 1 (VILIP1) belongs to a group of neuronal calcium sensor (NCS) proteins and contains two functionally active EF-hand motifs for the binding of Ca2+. All members of the NCS family contain a myristol residue which, dependent on a conformational change upon Ca2+-binding, interacts with cellular membranes. Cytosolic VILIP-1 has been shown to translocate Ca2+-dependently to the plasma membrane, where it has been shown to directly or indirectly affect cellular cGMP and cAMP levels and to modulate α4β2-nicotinergic acetylcholine receptors.
We found VILIP1 to be specifically enriched in an aggregate fraction of SOD1(G93A) and SOD1(G85R) overexpressing mice at disease onset and endstage, but not in SOD1(WT) overexpressing mice and non-transgenic littermates. Furthermore we could show that in SOD1-mt overexpressing mice VILIP1 localization to the plasma membrane was decreased and the protein was more uniformly distributed to the cytosol.
Considering that VILIP-1 localization is sensitively modulated by intracellular calcium levels, and VILIP-1 trapped in aggregates might not be functionally active, a reduction of available VILIP-1 protein level provides an interesting link between the role of protein aggregation and glutamate excitotoxicity in ALS.

Abstract: Amyotrophic lateral sclerosis (ALS) is devastating disease that 90% of the cases is sporadic with unknown origin. Studies carried out with postmortem tissue from sALS and fALS patients clearly show accumulation of oxidative damage to proteins, lipids, and DNA indicating a direct role of oxidative stress. Glutathione (GSH) which is considered to be the most prevalent and important intracellular non-protein thiol/sulfhydryl antioxidant in mammalian cells is reportedly decreased in spinal cord of ALS patients. We aimed to test the hypothesis that impaired GSH de novo synthesis can trigger motor neuron degeneration by creating conditional CNS knockout of glutamate cysteine ligase, catalytic subunit (Gclc), named as NEGSKO mouse. With 40-65% reduced GSH level in brain and spinal cord, NEGSKO mice developed a gait abnormality by approximately ~22 days of age with slightly reduced body size and body weight, and have a postnatal life expectancy of approximately 5 weeks. Histology at postnatal day 28 indicated, motor neurodegeneration was accompanied with increased apoptosis (TUNEL stain), activated caspase 3, cytochrome C translocation into cytoplasm, decreased cholinergic neurons with ChAT stain, muscle atrophy and denervation. EMG done in gastrocnemious muscle at postnatal day 28 showed numerous fibrillation potentials indicative of loss of muscle fiber innervation and fasciculations. The most intriguing finding is that NEGSKO mouse have increased neuronal TDP-43 fragmentation and translocation from nucleus to cytoplasm that colocalizes with elevated ubiquitination, a characteristic finding in sALS. Further mechanistic characterization indicates that mitochondrial GSH level was significantly reduced (~40% vs. wild type), and mitochondrial function was impaired, in particular state IV of mitochondrial electron transporter chain (ETC). Similar conclusions were obtained with a human neuroblastoma cells showing that TDP-43 was translocated into cytoplasm when cells Gclc was knockdown with shRNA, but not glutamate cysteine ligase, modifier subunit (Gclm). These results implicate the key role Gclc in the maintaining mitochondrial GSH homeostasis. Taken together, NEGSKO mice, with impaired GSH synthesis, closely resemble sALS, and are expected to serve as a novel mouse model for sALS research and testing of pharmacological inhibitors of neuronal apoptosis and degeneration.

Title: Tin protoporphyrin XI, a competitive inhibitor of Heme oxigenase, exacerbates the cellular damage induced by an intrastriatal infusion of quinolinic acid to rats

Authors: *A. L. COLÍN GONZÁLEZ[1], M. OROZCO-IBARRA[1], M. CHANEZ-CARDENAS[1], D. SILVA-ADAYA[1], A. SANTAMARIA[1], J. PEDRAZA-CHAVERRI[2], P. D. MALDONADO[1]

Abstract: Under physiological conditions, the tryptophan metabolite quinolinic acid (QA) is known to play a role in brain development. However, increased QA concentrations contribute to dysfunction of the CNS in certain disorders such as Huntington's disease (HD), dementia associated with HIV-AIDS, cerebral ischemia, epilepsy and multiple sclerosis. After an intrastriatal infusion of QA to rats and primates, overactivation of N-methyl-D-aspartate (NMDA) receptors yields excitotoxicity, oxidative stress and mitochondrial dysfunction, which altogether contribute to trigger a wide variety of toxic effects with biochemical, behavioral and neuropathological alterations similar to those of HD. Noteworthy, both in the brains of HD patients and QA-lesioned animals, increased expression levels of Heme oxygenase 1 (HO-1) can be found. This enzyme can exert a dual role, as it can be either protective or deleterious in the CNS. A large body of evidence indicates that HO-1 overexpression affords cellular antioxidant protection due to 1) a decrease in the concentration of its pro-oxidant substrate, 2) an increase in the antioxidant bilirubin, and 3) an increase in ferritin synthesis. On the other hand, a high expression of HO-1, and consequently, an increase in its activity, may also result in a pro-oxidizing atmosphere due to a release of Fe2+, a response that depends on the intensity of activation and the cellular microenvironment. In this work we evaluated the role of HO-1 in animals intrastriatally infused with QA (240 nmol/μL). For this purpose, the tin protoporphyrin IX (SnPP), a well-known HO inhibitor, was administered to rats (30 mmol/kg, i.p.). The ratio of cell damage, the content of carbonyl groups as an indicator of oxidative damage, and the HO activity were all quantified 3 days after the QA injection. QA induced HO-1 at 3 days after its infusion. The administration of SnPP to animals treated with QA inhibited the HO activity while increased the content of carbonyl groups and cell damage when compared to the group receiving QA alone. These data strongly suggest that HO-1 might be exerting a protective role in the toxic paradigm evoked by QA in rats.

Title: Proteasome function in the longevity *Drosophila* mutant methuselah

Authors: *J. GAO[1], C.-H. YEH[2], M. JANSEN[2], C. CHAN[2], S. DODDI[2], M. FIGUEIREDO-PEREIRA[2], T. SCHMIDT-GLENEWINKEL[2]

Abstract: The ubiquitin-proteasome system (UPS) plays a central role in turning over 80-90% of intracellular proteins as well as in the degradation of misfolded proteins. With increasing age the UPS declines in activity in the nervous system which commonly affects steady state protein dynamics and causes enhanced protein aggregation. Most neurodegenerative disorders are associated with aggregates of ubiquitinated proteins, such as Lewy bodies in Parkinson's disease and neurofibrillary tangles in Alzheimer's disease. Here we investigate the proteasome function of the Drosophila longevity mutant, methuselah (mth) which encodes a putative G-protein coupled receptor. mth mutant flies exhibit a 35% increase in average lifespan and are resistant to numerous stressors including high temperature, starvation, and oxidants. The underlying mechanism for the increase in longevity is unknown. Our studies are the first to show that the mth mutation delays the decline in proteasome activity caused by aging. The proteasome activity and proteasome protein level of the parent control line, w1118 declines sharply during the aging process. However, the proteasome activity and proteasome level of mth are maintained at advanced age. Interestingly, proteasome activity, proteasome protein level, individual proteasome subunit level as well as ATP level were higher in w1118 than in mth at corresponding young age but differed at the oldest age. We also found that the ubiquitinated proteins and aggregates are reduced in mth mutants when compared with the w1118 strain at each age group. These results are similar to the effects of dietary restriction, which extends lifespan by reducing the rate of metabolism and mortality. Our studies will contribute to clarify the role of mth gene in the aging process and the relationship between the UPS pathway and aging.

Title: Sympathosensory coupling in aged mice that over express nerve growth factor

Authors: *L. J. SMITHSON[1], M. D. KAWAJA[2]
[1]Kingston, ON, Canada; [2]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Since its discovery over 50 years ago, nerve growth factor (NGF) has been shown to induce directional axonal growth of postganglionic sympathetic neurons, neural crest-derived sensory neurons, and basal forebrain cholinergic neurons. In this study, we investigated the effects of age on sympathetic perineuronal plexuses formation in sensory ganglia of transgenic mice that have elevated levels of NGF in cells expressing the glial fibrillary acidic protein promoter (GFAPpr). Our group has previously shown the presence of tyrosine hydroxylase (TH)-immunopositive perineuronal plexuses around a subset of sensory somata of 2-3 month old GFAPpr-NGF mice. This sympathosensory coupling has been linked to the onset of neuropathic pain. In this current study, we demonstrated morphological changes (at both light and electron microscopy levels) of TH-immunopositive perineuronal plexuses in sensory ganglia of aged (i.e., 11-13 month and 16-18 month old) transgenic mice, compared to younger (i.e., 2-3 month old) GFAPpr-NGF mice. Double immunolabeling revealed an association between cfos- and TNFα-immunopositive reactive satellite glial cells (and some Iba1-immunopositive reactive macrophages) and TH-immunopositive plexuses in aged mice, compared to younger transgenic mice. In addition, TH-immunopositive perineuronal plexuses in aged transgenic mice appeared swollen or degenerated and were associated with dead or dying sensory neurons. No significant differences were observed in Kir4.1 expression in satellite glial cells among the different age groups of GFAPpr-NGF mice. Our results are the first to report changes in the morphology of perineuronal plexuses in aged mice. These results suggest that the presence of perineuronal plexuses of sympathetic axons around sensory somata may be slowly damaging the associated sensory neurons. That is, sympathosensory coupling in aged mice likely compromises the function of sensory neurons, which may have profound implications for neuropathic pain.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disease that causes progressive memory and cognitive decline during middle to late adult life. The AD brain is characterized by deposition of amyloid β peptide (Aβ), which is produced from amyloid precursor protein by β- and γ-secretase-mediated sequential cleavage. Induced pluripotent stem (iPS) cells potentially provide an opportunity to generate a human cell-based model of AD that would be crucial for drug discovery as well as for investigating mechanisms of the disease.
We differentiated human iPS (hiPS) cells into neuronal cells expressing the forebrain marker, Foxg1, and the neocortical markers, Cux1, Satb2, Ctip2, and Tbr1. The iPS cell-derived neuronal cells also expressed amyloid precursor protein, β-secretase, and γ-secretase components (Presenilin 1, Nicastrin, Pen-2, and Aph-1) and were capable of secreting Aβ into the conditioned media. Aβ production was inhibited by β-secretase inhibitor, γ-secretase inhibitor (GSI), and an NSAID; however, there were different susceptibilities to all three drugs between early and late differentiation stages. At the early differentiation stage, GSI treatment caused a temporal increase at lower dose (Aβ surge) and drastic decline of Aβ production in three hiPS/human embryonic stem cell lines. These results indicate that the hiPS cell-derived neuronal cells express functional β- and γ-secretases involved in Aβ production; however, anti-Aβ drug screening using these hiPS cell-derived neuronal cells requires sufficient neuronal differentiation.

Title: Blood transcriptomic biomarkers of AD patients treated with EHT 0202

Authors: *L. DESIRE, J. CARRIÈRE, P. BEURDELEY, M. PANDO
Exonhit SA, Paris, France

Abstract: Monitoring patients genomic expression in clinical trials for Alzheimer's Disease (AD) can assist trial design and treatment response analysis. Here, we report on the identification in AD patients of blood-based transcriptomic signatures associated with treatment response of EHT 0202, a new compound with potential disease-modifying and symptomatic properties.
EHT 0202 recently completed a 3-month, placebo-controlled, Phase IIA study aimed at determining the clinical safety, tolerability and exploratory efficacy of EHT 0202 (40 and 80mg bid) as adjunctive therapy to one cholinesterase inhibitor in mild to moderate AD patients. During the study, blood samples were collected from each randomized patient at different time points, notably before treatment initiation and at study completion. Using sixty AD patients having either responded or declined during the study period with regards to ADAS-cog total score, we report on the identification of blood-based transcriptomic signatures associated with treatment response of EHT 0202, using Exonhit's SpliceArray^{TM}. This new generation of microarray extends transcriptomic profiling to the monitoring of alternative splicing.
Two transcriptomic signatures were identified: a predictive (prior to treatment), and efficacy profile (post-treatment) from peripheral blood specimens that correlated with treatment response and efficacy of EHT 0202, respectively. In the patients responding to EHT 0202, the pre-treatment (baseline) signature showed activation of pathways related to AD, CNS disorders, diabetes, inflammation, and autoimmunity, while the post-treatment signature indicated reduced activation of these pathways with induced metabolic and transcription stimulation.
These signatures should be replicated in a larger patient population. Nevertheless, this pilot study demonstrates the utility of blood transcriptomic signatures used as biomarkers for predicting patient response or monitoring efficacy, through the administration of a therapeutic drug in a complex disease such as AD. For EHT 0202 or other AD drugs, such biomarkers may help to improve strategies to better: identify appropriate patient populations for treatment, understand the drug mechanism of efficacy, and/or clarify the inherent subjectivity in most clinical endpoints used in this disease.

Lab., Upton, NY; [2]Dept. of Psychology, Stony Brook Univ., Stony Brook, NY; [3]Dept. of Psychology, SUNY Suffolk, Long Island, NY; [4]Dept. of Physiol. and Pharmacol., Oregon Hlth. and Sci. Univ., Portland, OR; [5]Lab. of Neuroimaging, NIDA, Bethesda, MD

Abstract: Dopamine (DA) is involved in a variety of brain functions including reward, locomotion, emotion, cognition, and memory (Jaber et al. 1996). Age-related decreases in DA D_2 receptors (*Drd_2)* have previously been associated with decreases in motor function (Umegaki et al. 2003). Exposure to an enriched environment (EE) has been widely implicated in an increase of lifespan, physical performance, and cognitive function (Warren et al. 1982). This study examined the role and interaction of *Drd_2* with an EE on lifespan and locomotor activity. ***Methods***: Male and female wild-type (*Drd_2* +/+), heterozygous (*Drd_2* +/-), and knockout (*Drd_2* -/-) mice were divided into two housing groups, an enriched environment (EE) and a deprived environment (DE). EE mice were group housed (4-6 mice) with access to a running wheel, an igloo, and an exploratory tunnel while DE mice were deprived of these objects and were single housed in a standard cage. Beginning at 20 weeks of age, all mice were measured bi-weekly for body weight and spontaneous locomotor activity. When mice approached their endpoint, they were euthanized and brain tissue was collected for future analysis. ***Results***: While final results

will be presented at the meeting, the majority of the results at this point show the following: Lifespan: Overall, *Drd$_2$* +/+ EE mice lived about 20% (p<0.001) longer than their DE counterparts (32% in males; p<0.01, 13% in females; p<0.05); whereas the lifespan in *Drd$_2$* +/- EE and *Drd$_2$* +/- DE mice was not found to be statistically significant (p>0.05). Finally, the *Drd$_2$* -/- mice showed no significant differences in lifespan between EE and DE mice (p>0.05). Bodyweight: Overall, when comparing within the DE housed mice, *Drd$_2$* +/- and *Drd$_2$* -/- mice weighed more than *Drd$_2$* +/+ mice by 10% and 9% respectively (p<0.05 for both). Comparison within the EE housed mice showed no significant differences (p>0.05).
Locomotor Activity: *Drd$_2$* +/+ and *Drd$_2$* +/- EE mice showed greater spontaneous locomotor activity compared to *Drd$_2$* -/- EE mice (33% and 28%, respectively; p<0.001 for both). Although *Drd$_2$* -/- DE mice showed 29% more locomotor activity compared to their EE counterparts (p<0.001), this was primarily influenced by the female mice (48%; p<0.001), since this trend was not seen in male mice, which was statistically not significant (p>0.05). In conclusion, these results show that *Drd$_2$* plays an important role in interaction with an enriched environment to produce significant changes in lifespan, body weight and locomotor activity.

Title: Identification of molecular mediators in the dysregulation of aged microglia

Authors: *S. C. HOPP[1], H. M. BROTHERS[2], I. BARDOU[2], R. M. KAERCHER[2], G. WENK[2]
[1]Neurosci., Ohio State Univ., Columbus, ; [2]Psychology, Ohio State Univ., Columbus, OH

Abstract: Neuroinflammation is a normal process that occurs in the brain in response to disease and injury. One of the primary effector cells of neuroinflammation are microglia, the resident macrophages of the CNS. Microglia activation can exert either neuroprotective or neurodegenerative effects in the CNS. As such, there are two general phenotypes of activated microglia. The first, classical activation (M1), is associated with pro-inflammatory markers and destruction of threats such as bacteria. The second, alternative activation (M2), is associated with

anti-inflammatory markers and the repair of surrounding tissue. Chronic classical activation of microglia is generally maladaptive, leading to neuronal death and decreases in neurogenesis. Interestingly, activated microglia are observed in aged rats as well as old humans before the onset of Alzheimer's disease in areas where degeneration usually occur, implicating that their dysregulation plays a role in disease pathogenesis. We hypothesize that a cyclic relationship between glutamate, pro-inflammatory cytokines, and Alzheimer's biomarkers exists. Here, we compare the inflammatory response of the aged rat brain to acute application of IL-1β, a pro-inflammatory cytokine that has been linked to Alzheimer's disease. Following acute injection of IL-1β, we examined the time course of biomarkers. Using multiplexed magnetic bead immunoassays, we measured 15 rat cytokines associated with M1 and M2 microglia phenotypes. We also analyzed mRNA expression of these and other inflammatory biomarkers using qPCR to confirm changes in cytokine expression. We found age- and treatment-dependent changes in the levels of cytokines expressed at the various time points. Our findings contribute to the overall understanding of the key molecular mediators in the dysregulation of neuroinflammation in aging, which is ultimately important in the development of treatments for age-related neurodegenerative diseases.

Title: Development of a striatum modeling and simulation platform to identify treatments for Huntington's disease

Authors: *F. J. PERNOT[1], R. GREGET[1], S. BISCHOFF[1], J.-M. C. BOUTEILLER[1,2], M. BAUDRY[1,3]
[1]RHENOVIA PHARMA, Mulhouse, France; [2]Biomed. Engin., USC, Los Angeles, CA; [3]Grad. Col. of Biomed. Sci., Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Huntington's disease (HD) is caused by an autosomal dominant mutation of the huntingtin gene. One of the major difficulties in identifying efficacious therapeutic agents to treat this disease is its complexity, as highlighted by the broad spectrum of multiple and often opposite pathological syndromes. In order to improve efficacy and limit the side effects of therapeutic agents new and better targets (or combinations of targets) need to be identified. As a first step, Rhenovia is developing a computational model of striatal GABAergic medium spiny neurons (MSN), which incorporates glutamatergic terminals originating from cortico-striatal inputs, and dopaminergic terminals from the nigro-striatal pathway. These synapses exhibit a large number of molecular targets that collectively regulate the activity of MSNs and thereby participate in the control of motor activity. The model was first validated by reproducing the features of glutamatergic and dopaminergic transmission under various stimulation conditions. In particular, the model reproduced the pattern of dopamine release under various stimulation frequencies and in the presence of dopamine transporter blockers. In addition, the model was used to determine the effects of various compounds affecting glutamatergic and dopaminergic targets on second messenger pathways in MSN dendritic spines. The model was also used to determine the role of presynaptic and postsynaptic dopaminergic receptors on the control of dopamine release and cAMP dynamics under a variety of experimental conditions. A major benefit of our computational framework has the potential to: (i) integrate the large knowledge base of HD biology to create pathological models; (ii) make data-based predictions about the success of drug development programs; (iii) predict potential clinical success of different drug targets; (iv) predict new drug potential side effects and (v) determine mechanism-based combination principles.

Title: Elevated 4-hydroxyhexenal in Alzheimer's disease (AD) progression

Authors: *M. BRADLEY[1], S. XIONG-FISTER[2], M. A. LOVELL[1]
[1]Chem., [2]Univ. of Kentucky, Lexington, KY

Abstract: Oxidative damage to nucleic acids, proteins, and lipids is not only a feature of normal aging but is associated with many neurodegenerative diseases, including Alzheimer's disease (AD). Lipids are particularly vulnerable to oxidative damage by reactive oxygen species (ROS) resulting in compromised integrity of cellular membranes and the generation of a variety of diffusible aldehydic by-products. Toxicity of α,β-unsaturated aldehydes including 4-hydoxynonenal and acrolein has been established in culture models and levels of both are elevated in the progression of AD. More recently 4-hydroxyhexenal (HHE) a third α,ß-unsaturated aldehydic by-product of peroxidation of docasahexaenoic acid (DHA) peroxidation has been identified. The current study aims to quantify levels of extractable and protein-bound HHE during the progression of AD in both vulnerable (hippocampus/parahippocampal gyrus (HPG) and less vulnerable brain regions (superior and middle temporal gyrus (SMTG) and cerebellum (CER). Levels of extractable HHE were quantified using gas chromatography mass spectrometry with negative chemical ionization (GC/MS/NCI) and protein-bound levels of HHE were determined by dot blot immunochemistry with an HHE specific antibody. Toxicity and glucose uptake were assessed in response to HHE treatment in primary cortical neurons. Levels of both extractable and protein-bound HHE were significantly elevated early in disease progression in the HPG and showed a significant positive correlation with levels of PBS soluble Aβ1-42 and FA soluble Aβ1-40. Treatment of primary cortical neurons with HHE lead to time- and concentration- dependent decreases in neuron survival. Treatment of primary cortical neurons with sub-toxic concentrations of HHE led to significant impairment in glucose uptake. These data suggest HHE is generated early during the pathogenesis of AD with potentially detrimental cellular effects further supporting the hypothesis that oxidative stress is an early event in the pathogenesis of AD.

Title: Tyr682 in the APP intracellular domain regulates cholinergic function and cognitive performance

Authors: *C. MATRONE[1], S. LUVISETTO[1,2], L. LA ROSA[1], R. TAMAYEV[2], L. D'ADAMIO[2]
[1]Inst. of Mol. Biol. and Neurobio., Natl. Council of Res., Rome, Italy; [2]A Einstein Med. Sch., New York, NY

Abstract: Processing of Aβ-precursor protein (APP) plays an important role in Alzheimer's Disease pathogenesis. The APP intracellular domain contains residues important in regulating APP function and processing, in particular the 682YENPTY687 motif. To dissect the functions of this sequence in vivo, we created an APP knock-in allele mutating Tyr682 (Y682) to Gly (APPYG/YG mice). This mutation alters processing of APP and TrkA signaling, and leads to postnatal lethality and neuromuscular synapse defects when expressed on an APP-like protein 2 knock-out background. The dramatic alterations present in mice bearing this mutation prompted us to characterize further the APPYG/YG mice. Here, we show that APPYG/YG mice develop aging-dependent decline in cognitive and neuromuscular functions. This phenotype correlates with a progressive reduction in cholinergic tone and TrkA levels, suggesting a mechanistic connection between cholinergic tone depression, TrkA signaling deficits, cognitive and neuromuscular performance decline of APPYG/YG mice. The profound deficits caused by the Y682 mutation underscore the biological importance of APP and indicate that APPYG/YG are a valuable mouse model to study APP functions in physiological and pathological processes.

Title: Short-term caloric restriction initiated at different ages had minimal effect on activation of Nrf-2 pathway

Authors: *N. THANGTHAENG, N. SUMIEN, M. J. FORSTER
Pharmacol. and Neurosci., Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Caloric restriction (CR) has been reported to confer health benefits, prolonged lifespan and attenuates age-related brain dysfunction. These outcomes have been hypothesized to be the results of alteration of redox homeostasis and reduction in oxidative damage. The purpose of this study was to determine if short-term CR affects antioxidant and detoxification response via the activation of the NF-E2-related factor 2 (Nrf2) pathway in different brain regions. Three age groups of C57BL/6J males, young (3 mos), middle-aged (12 mos), and old (19 mos) were assigned to either ad libitum (AL) or 30% CR. After four-months, nuclear translocation of Nrf-2 (n=4), and activities of Nrf-2 down-stream target genes (n=5-8) such as glutamate-cysteine ligase (GCL), and glutathione S-transferase (GST), and glutathione levels (GSH; n=6-9) were measured within the cerebral cortex (CX), cerebellum (CB), hippocampus (HP), and striatum (ST). Furthermore, aldehyde reactive probe (ARP) was used to assess oxidative damage proteins in each region (n=5-8). With age, Nrf-2 translocation was enhanced only in CB and HP, GST and GCL activities were increased, and GSH concentrations showed a small decrease. The short regimen of CR had little effect on Nrf-2 activation and its downstream effectors, except in CB and HP where CR attenuated age-related induction of Nrf-2. However, CR did not seem to change GSH concentrations in any region. The current results suggest that while CR may be able to activate Nrf-2 and promote an antioxidant and detoxification response in a region-specific manner; this effect did not have any impact on the level of reduced glutathione.

Title: Circuit specific functions of cannabinoid CB1 receptor in aging

Authors: A. LEGLER[1], R. LERNER[1], A. BILKEI-GORZÓ[2], B. LUTZ[1], *K. MONORY[1]
[1]Inst. of Physiological Chem., Univ. Med. Ctr. of the Johannes Gutenberg Univ., Mainz, Germany; [2]Inst. of Mol. Psychiatry, Univ. of Bonn, Bonn, Germany

Abstract: Aging of the brain holds the risk of neurodegenerative diseases and cognitive decline. As, thanks to the modern medical standards, the human population is getting older and older, this is an increasingly important theme for neuroscientists and society as a whole.
The endocannabinoid system (ECS) has emerged as a multifunctional neuromodulatory system, implicated in a plethora of physiological and pathophysiological processes. Among others it plays a role in learning, memory, neuroprotection and metabolism. By analyzing rodents in various memory tests, it has been shown that the ECS is required in acquisition and/or extinction of memories. The most prominent receptor that mediates the effects of endocannabinoids in the brain is the cannabinoid type 1 (CB1) receptor. This G protein coupled receptor is most abundant in the brain, but is also found in peripheral organs. Lack of the CB1 receptor leads to enhanced neuroinflammation in the hippocampus during aging.
We aim at understanding the dynamics of the activity status of the ECS in the adult mouse brain during the progression of normal aging and to dissect which neuronal circuits containing CB1 receptors are receptive to these age-dependent effects. By testing hippocampus-dependent behavior in conditional mutant mice lacking the CB1 receptor in cortical glutamatergic or GABAergic neurons, we will unravel the role of the ECS in age-dependent cognitive decline. A gene expression study of the ECS components via quantitative PCR shall elucidate age-related variations of the system. A better understanding of how the ECS in involved in aging could provide new therapeutical options for age related diseases.

Title: Tau oligomer protease, a therapeutic target for Alzheimer’s disease

Authors: J. G. MOE, P. LOPEZ, D. ROMERO, *E. J. DAVIDOWITZ
Oligomerix, Inc., New York, NY

Abstract: Tau is a microtubule binding protein that normally functions in axons to maintain microtubule structure but is hyperphosphorylated in AD facilitating its dissociation from microtubules and accumulation in the somatodendritic compartment where it can aggregate (Iqbal et al. 2010). Neurofibrillary tangles, primarily composed of tau protein are a pathological hallmark in Alzheimer's disease (AD). However, the oligomeric forms of tau appear to be most closely associated with neuronal loss and memory impairment in mouse models of tauopathy (Berger et al. 2007; Yoshiyama et al. 2007). Tau oligomers were also found to accumulate in human AD specimens (Maeda et al. 2006; Patterson et al. 2011; Lasagna-Reeves et al. 2012). Importantly, extracellular tau oligomers have been shown to cause memory impairment and toxicity in mice inhibiting formation of long-term potentiation in hippocampal slices and formation of associative fear memory (Fá et al. 2010) and to induce neurodegeneration by affecting mitochondrial and synaptic function (Lasagna-Reeves et al. 2012). However, the particular structure and mechanism by which tau oligomers exert their deleterious effects has not been determined. We have found that upon the formation of oligomeric structures tau acquires the additional function of a protease leading to self-cleavage and the ability to cut other proteins. Here, we describe work characterizing this activity, the development of tools for studying its role in disease, and approaches for targeting tau protease for the development of small molecule drugs and antibody therapeutics.

Title: Cortical and hippocampal expression of insulin-degrading enzyme and neprilysin in normal aging: Implications for amyloid-beta clearance

Authors: *M. C. MILLER[1], A. A. MESSIER[2], D. P. OSGOOD[2], V. HOVANESIAN[4], J. T. MACHAN[5], C. CHIU[2], E. G. STOPA[3], C. E. JOHANSON[2], G. D. SILVERBERG[2]
[1]Rhode Island Hospital/ Brown Univ., North Attleboro, MA; [2]Neurosurg., [3]Pathology, Brown

University/ Rhode Island Hopsital, Providence, RI; [4]Core Image Analysis Lab., [5]Biostatistics, Rhode Island Hosp., Providence, RI

Abstract: Background: Age is the single most important risk factor in the accumulation of amyloid-beta (Aβ) peptide in both normal aging and non-familial Alzheimer's disease (AD). Impaired clearance of Aβ from the brain interstitial fluid has been postulated to be an important component in the accumulation of brain Aβ in both processes. It has been recognized that enzymatic degradation of Aβ occurs in situ by way of enzymes such as neprilysin and insulin-degrading enzyme (IDE). However, previous studies seem to indicate that this local degradation of Aβ accounts for only a minimal amount of clearance at physiological concentration in both aging and AD. In this study, we measured neprilysin, IDE, and Aβ peptide levels in the frontoparietal cortex and hippocampus across normal aging in Fischer 344/ Brown-Norway hybrid rats.
Methods: Rats at selected ages from 3 to 36 months were analyzed by: (A) immunohistochemistry (IHC) and (B) Western blotting for cortical and hippocampal neprilysin and IDE protein expression. Software-assisted and manual neuronal cell counting was performed on the IHC-stained sections, and optical density readings were obtained from the immunoblots at all age points. In addition, cortical Aβ40 and Aβ42 concentrations were measured by ELISA.
Results: The concentrations of cortical Aβ40 and Aβ42 increased significantly with age ($p<0.001$), with the sharpest rise occurring from 9 to 12 months. In contrast, IDE expression did not significantly change across any of the age groups tested by both IHC and immunoblot. Neprilysin expression did not significantly change by immunblot, but a significant decrease in total number of immunopositive hippocampal neurons (after 9 months of age) and cortical neurons (after 12 months of age) was observed. However, it is important to note that these changes manifest after Aβ has already begun to increase (initially happening between 6 and 9 months of age).
Conclusions and future directions: Our results suggest that in aging, in situ degradation does not play a major role in Aβ clearance, but rather, the majority of Aβ clearance is by transport across the brain-fluid barriers and by the bulk flow of cerebrospinal fluid (CSF). These data are in keeping with our previous finding of a strong relationship between Aβ accumulation and the expression of Aβ transporter genes at the blood-brain and blood-CSF barriers.
Conflict of interest declaration: No conflict of interest to declare.

Title: TZDs may offer neuroprotection through a mitochondrial target (mTOT)

Authors: A. DIVAKARUNI[1], S. WILEY[1], A. ANDREYEV[1], G. ROGERS[2], J. COLCA[3], *A. N. MURPHY[1]
[1]UCSD, LA JOLLA, CA; [2]Seahorse Biosci., Billerica, MA; [3]Metabolic Solutions Develop. Co., Kalamazoo, MI

Abstract: Thiazolidinediones (TZDs), such as pioglitazone, promote neuroprotection in a wide variety of preclinical models of neurodegeneration including Parkinson's and Alzheimer's Disease and stroke, and are in human trials for these indications. As PPAR-γ agonists, however, these TZDs cause marked side effects that can be clinically prohibitive (including plasma volume expansion, increased adiposity, congestive heart failure, and cardiovascular risk). A target of insulin sensitizers located in the mitochondrial inner membrane, mTOT, was recently identified and may contribute to the neuroprotective and insulin sensitizing pharmacology of TZDs.

We find that TZDs previously approved for treating type 2 diabetes (pioglitazone, rosiglitazone, and troglitazone) selectively inhibit pyruvate oxidation to varying degrees in both permeabilized rat cortical neurons ans also human and rodent myocytes. This action is also shared by a prototype PPARg-sparing TZD, MSDC-0160, which was designed to have a more selective interaction with the mitochondrial target and is now in clinical trials for both type 2 diabetes and Alzheimer's disease.

Clinically relevant concentrations of the drug (1uM<Kd<7uM) selectively inhibit respiration on pyruvate, but have no effect on either alternative Complex I-linked substrates, such as glutamate and palmitoylcarnitine, or the complex II-linked substrate succinate.

Our data suggest mTOT is a heretofore uncharacterized regulator of mammalian pyruvate oxidation. Moreover, the inhibition of pyruvate oxidation via TZD binding to mTOT may be a crucial mediator of the effects of TZDs.

Title: Early-life deficiency of growth hormone and IGF-1 affects outcomes of endothelin-induced cerebral ischemia

Authors: H. YAN[1], M. MITSCHELEN[1], K.-M. FUNG[2], J. FARLEY[1], Z. UNGVARI[1], A. CSISZAR[1], J. P. WARRINGTON[1], *W. E. SONNTAG[3]

Abstract: Numerous experiments and clinical evidence have shown that age-related IGF-1 deficiency negatively affects the health span in the aged population as well as the morbidity and mortality of cerebrovascular disease. However, recent studies suggest that peripubertal deficiency of growth hormone (GH) and IGF-1 increases lifespan. Nevertheless, the cerebrovascular effects of early-life GH/IGF-1 deficiency remain controversial. To investigate the effects of IGF-1 deficiency on the outcome of cerebral ischemia, dwarf rats with GH/IGF-1 deficiency and their normal heterozygous littermates (HZ) as well as dwarf rats injected with GH were subjected to endothelin-induced stroke. Endothelin-1, a potent vessel constrictor, was unilaterally injected proximal to the middle cerebral artery. Neurological deficits and sensorimotor function were monitored on post-surgical days 1 and 3. After behavioral tests on

day 3, animals were euthanized and the brains were cryosectioned. Sections were evaluated for infarct volume, neurogenesis, oxidative stress, inflammation, and gliosis. Animals in the three groups did not differ in levels of endothelin receptors. Compared to HZ and GH-replaced groups, dwarf animals demonstrated significantly smaller infarct volume, a reduction in Nestin-positive immature neurons in the peri-infarct region and reduced levels of 4-HNE (a marker of lipid oxidation), MMP9 (an inflammatory marker), and activated microglia (assessed by *Iba-1*$^{+}$ staining) migrating into the infarct core. Our results indicate that in response to ischemic challenge animals with early-life IGF-1 deficiency accumulate less oxidative stress and signs of inflammation. Our results provide evidence that early-life GH and IGF-1 deficiency has unique effects on infarct volume and recovery in response to endothelin induced cerebral ischemia.

Title: Exogenous nicotinamide application prevents neurite degeneration by the mechanism independent from nicotinamide adenine dinucleotide salvage pathway *in vitro* DRG neurons

Authors: *S. TOKUNAGA[1,2], T. ARAKI[1,2]
[1]Natl. Inst. of Neurosci., NCNP, Kodaira-Shi, Japan; [2]Waseda Univ., Shinjuku-ku, Japan

Abstract: Axonal degeneration occurs in various neurological disorders, including stroke, Parkinson's disease and peripheral neuropathies. Studies in animal models of neurological disorders indicate that axonal degeneration precedes the appearance of disease symptoms, suggesting that delaying the degeneration process can prevent the progression of disorders. A previous study demonstrated that exogenous application of high conc nicotinamide (Nam) or nicotinamide adenine dinucleotide (NAD) (> 5 mM) at the time of neurite transection can delay neurite degeneration concurrently with increased intracellular NAD level. Although Nam is utilized as a NAD precursor in salvage pathway in mammalian cells, Nam is also a potent natural modulator of several proteins, including cytokines and NAD-dependent protein deacetylases. To determine whether Nam-mediated neurite protection depends on NAD salvage pathway, we inhibited nicotinamide phosphoribosyltransferase (Nampt), which synthesizes the substrate for NAD biosynthetic enzyme from Nam in DRG neuron cultures and assessed the impact on the

protective effect of Nam exogenous application. We found that the inhibition of Nampt did not affect the protective effect by Nam exogenous application. In addition, we found that the decline of mitochondrial membrane potential after neurite transection was suppressed promptly after exogenous Nam application. These results suggest that Nam may exert neurite-protective effect through mitochondrial protection independently from NAD salvage pathway

Title: Apoaequorin protects neurons from ischemia and alters cytokine mRNA levels in rat hippocampus.

Authors: *E. L. HOCHSTETTER[1], J. A. DETERT[1], J. D. LESCHER[1,2], J. R. MOYER, Jr.[1,2]
[1]Psychology, [2]Biol. Sci., Univ. of Wisconsin Milwaukee, Milwaukee, WI

Abstract: During an ischemic attack, elevated levels of intracellular calcium can produce deleterious effects, up to and including cell death. Calcium binding proteins (CaBPs) are one mechanism by which cells sequester excess calcium. Aequorin is a CaBP isolated from the jellyfish Aequoria Victoria. We previously demonstrated that an intrahippocampal injection of apoaequorin (AQ, the CaBP component of aequorin) significantly protects hippocampal neurons from ischemic cell death. The neuroprotective effects of AQ were first observed at 24 hrs and endured for up to 48 hours. Interestingly, western blot analysis suggested that AQ protein levels dramatically decrease over this time period. Although the neuroprotective effects of AQ were strongest at 48 hrs, the relatively low level of AQ protein present at that time suggests that other factors may play a role in the ability of AQ to protect neurons from ischemic cell death. One possibility is that AQ administration leads to a change of levels of anti-inflammatory cytokines. Interleukin-10 (IL-10), an anti-inflammatory cytokine, has previously demonstated the ability to protect neurons from hypoxia in vitro. To test the hypothesis that cytokine expression may play a role in the neuroprotective effects of AQ, cytokine mRNA levels were measured at different time points following a single, intra-hippocampal administration of AQ. Twelve male F344 rats were bilaterally cannulated in the dorsal hippocampus. Following recovery, 4% AQ was injected unilaterally (vehicle in the other side, counterbalanced) and after 1, 24, or 48 hrs, the brains were

removed and the hippocampi dissected, placed on dry ice, and homogenized. RNA was isolated using Qiagen's RNeasy mini kit. Reverse transcription was performed using Qiagen's RT2 HT First Strand Kit-96 and qPCR was used to quantify IL-10 and β-actin. IL-10 was significantly increased in the AQ treated hemispheres at 1 hour ($t(14) = 5.30$, $p < .05$), but not 24 or 48 hours ($p > .05$) post injection. AQ treatment did not affect β-actin mRNA levels. Further PCR array analyses with Qiagen's RT2 Profiler Arrays for cytokines and chemokines were performed in an effort to evaluate whether other cytokines and chemokines are activated at these time points. Results suggest that multiple anti-inflammatory cytokine and chemokine mRNA levels change in a time-dependent manner following AQ administration. Ongoing studies are investigating IL-10 and IL-10Rα protein levels to determine how their time courses compare with those of the mRNA. Collectively, these results suggest that AQ is neuroprotective and that this neuroprotection may at least partly involve a neuroimmunomodulatory mechanism.

Title: Diffusion parameters in the brain and behavioral changes in hereditary hypertriglyceridemic rats

Authors: I. VORISEK[1], *L. VARGOVA[2], M. ORT[1], E. SYKOVA[2,1]
[1]Inst. of Exptl. Med. AS CR, Prague, Czech Republic; [2]Dept. of Neurosci., Charles University, 2nd Med. Fac., Prague, Czech Republic

Abstract: We studied the diffusion parameters in the brain and cognitive changes during aging in hereditary hypertriglyceridemic (HHTg) rats, an experimental non-obese model of insulin resistance. Cognitive decline in old age has been linked not only to neuronal loss and changes in the efficacy of synaptic signal transmission, but also to changes in extracellular diffusion, which affects extrasynaptic transmission. Changes in diffusion parameters during aging result mainly from structural rebuilding of astrocytic processes and the quantitative and qualitative changes of extracellular matrix (ECM) molecules.
The cognitive abilities of 4- and 21-month-old rats were assessed using the active allotethic place

avoidance (AAPA) test, in which an animal has to learn to avoid the prohibited sector in a rotating circular arena. Then, the apparent diffusion coefficient of water (ADC_W) was measured in the HHTg rats and Wistar control animals using diffusion-weighted magnetic resonance and a stimulated echo sequence. HHTg rats exhibited significantly increased glycemia, triglyceridemia and impaired glucose tolerance at the ages of 4 and 21 months. The AAPA test was performed 1.5 and 24 hours after training.

In the short-term memory test, aged HHTg rats performed better than age-matched controls (time of avoidance was 216 ± 20 s vs. 87 ± 15 s, n = 5). In the long-term memory test, the aged HHTg rats' performance was not significantly different from that of age-matched controls (104± 12 s vs. 113 ± 15 s, n = 5). There were no significant differences between young-adult HHTg and control rats: 233± 11 s vs. 238 ± 10 s (n = 6). ADC_W was measured in the cerebral cortex (CX) and hippocampal CA1area. ADC_W in young adult HHTg rats (CX: 615 ± 9 $\mu m^2 s^{-1}$, CA1: 754 ± 15 $\mu m^2 s^{-1}$, n=6) was not significantly different from that in age-matched controls (CX: 622 ± 13 $\mu m^2 s^{-1}$, CA1: 767 ± 18 $\mu m^2 s^{-1}$, n=6). In 21-month-old control rats, significantly lower values were observed: 578 ± 10 $\mu m^2 s^{-1}$ (CX), 718 ± 17 $\mu m^2 s^{-1}$ (CA1), n = 5. In contrast, aged HHTg rats did not exhibit a significant decrease in ADC_W: 606 ± 12 $\mu m^2 s^{-1}$ (CX), 750 ± 19 $\mu m^2 s^{-1}$ (CA1), n = 5.

We conclude, that the formation of long-term memories in aged HHTg rats is affected by aging to the same extent as in control rats. However, HHTg rats did not show a decline in short-term memory during aging, which could be related to preserved extracellular space diffusion. This might be due to changes of slowly metabolized ECM molecules (e.g. advanced glycation and different water content), which affect the extracellular volume and diffusion barriers and in turn extrasynaptic as well as synaptic transmission and cognitive functions.

Title: Promoting endogenous repair the aged brain following stroke

Authors: *N. SACHEWSKY[1], D. PICCIN[2], T. ZARIN[2], J. HUNT[2], C. MORSHEAD[2]
[1]Univ. Toronto, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Stroke is the third leading cause of death and disability in both Canada and the US. Seventy-five percent of strokes occur in individuals over the age of 65 and there are no current medical therapies for alleviating the chronic functional impairments that result. Regenerative strategies to repair the ischemically injured brain have not been fully realized or adapted to reflect the aged cohort of stroke patients. We have previously demonstrated that endogenous neural stem and progenitor cells (together termed precursor cells, NPCs) residing in the periventricular region of the adult forebrain can be activated with growth factors or the small molecule Cyclosporin A (CsA) in a permanent occlusion model of stroke, ultimately resulting in newly generated tissue and functional recovery in young adult animals. We have shown that CsA acts directly on NPCs to promote their survival by selectively inhibiting mitochondrial pore formation, thereby enhancing their survival. Reports suggest that the size of the NPC pool is depleted with age hence the efficacy of these endogenous stimulation strategies in the aged brain is not clear. We first examined whether NPCs derived from the young and aged brains were inherently different or whether the NPC niche could account for the apparent differences between young and aged brain. We transplanted young and aged NPCs into both young and aged brains and found that the decreased NPC migration and olfactory bulb neurogenesis seen in aged brain was completely independent of the transplanted cells indicating that the NPC niche dictated the behaviour of the transplanted cells. *In vitro* co-culture experiments confirmed these findings whereby aged NPCs plated to an overwhelming young environment resulted in a complete rescue of the total numbers of neural stem cells as shown by a rescue of the numbers of neurospheres back to the numbers observed from the young adult brain. Given that the total numbers of stem cells is unchanged with age, we reasoned that we could activate the endogenous cells using our endogenous stimulation paradigms. We demonstrated that CsA *in vitro* lead to a similar increase in the survival of NPCs from the aged brain as reported from the young adult brain. Moreover, in an endothelin-1 (ET-1) model of stroke, which closely parallels ischemia in humans by mimicking the loss of blood flow and the subsequent reperfusion of the lesion, CsA administration was able to activate aged NPCs *in vivo*, resulting in tissue regeneration and functional recovery in aged mice. These findings suggest that endogenous neural precursor activation holds great promise for cell-based strategies to treat stroke in a clinically relevant model and age cohort.

Abstract: Nanoparticles (NPs) are studied in a variety of biological systems, and the use of NPs as a novel approach to treat disease has been described in several experimental models, including cancer, eye diseases, cerebral palsy, diabetes and coronary artery disease. The focus of this project is to examine the toxicity of NPs used to deliver drugs to the brain. Coating NPs with surfactants, such as Tween 80, has been shown to facilitate the crossing of various biological barriers including the blood brain barrier (BBB). Poly(butylcyanoacrylate) (PBCA) NPs are biodegradable and can be loaded with anti-tumor drugs, such as doxorubicin and gemcitabine and coated with surfactants including polysorbates (Tween 80) or poloxamers. These drug-conjugated PBCA NPs have been successfully used to treat glioblastoma in animals, providing indirect evidence that the PBCA NP can cross the BBB. However, there are concerns that the Tween 80 surfactant coating may be toxic at therapeutic doses. A detailed characterization of PBCA-Tween 80 NP toxicity is important for the design and use of these NPs in drug delivery to the brain. In the present study, a cell co-culture model of the BBB consisting of primary rat brain astrocytes and endothelial cells was used to investigate gene expression patterns in co-cultures following exposure to (1) PBCA NPs coated with Tween 80; (2) PBCA NPs loaded with doxorubicin and coated with Tween 80; and (3) untreated controls. After six days in culture, co-cultures were treated with PBCA-Tween 80 or PBCA-Tween 80-doxorubicin NPs at the following concentrations: 7.8 μg/ml, 31.25 μg/ml and 125 μg/ml. RNA was collected 8 hours post-treatment and analyzed for expression of 84 apoptosis-related genes using Apoptosis RT^2 Profiler PCR Arrays. The results indicate that co-cultures exposed to PBCA-Tween 80-doxorubicin NPs at the two lower concentrations exhibit a downregulation of a number of apoptosis-related genes relative to controls. Specifically, co-cultures treated at 7.8 μg/ml PBCA-Tween 80-doxorubicin NPs had a significant downregulation of *Cflar, Ripk, Cradd, Aven, Mapk8ip1, Nfkb1* and *Bcl2*. Co-cultures treated with 31.25 μg/ml PBCA-Tween 80-doxorubicin NPs had a significant downregulation of *Ripk, Tradd, Traf4, Cradd, Aven* and *Sphk2,* whereas very few changes were observed in the expression of apoptosis-related genes in co-cultures exposed to PBCA-Tween 80 NPs. These results indicate that PBCA-

Tween 80 NPs induce a much lower level of toxicity than those loaded with doxorubicin in this co-culture system and that use of Tween 80 as a NP coating for drug delivery systems should be further evaluated.

Title: Could mechanical obstruction by slowly degenerating nerve debris cause a delay in axon regeneration in aged animals?

Authors: *H. KANG, J. W. LICHTMAN
Mol. and Cell. Biol., Harvard Univ., CAMBRIDGE, MA

Abstract: In the aging population, delay in functional recovery following motor impairment is a major health concern because it restricts mobility and independence. However the underlying causes of this delay are not known. Ideas such as an intrinsic decline in a peripheral neuron's ability to regenerate, or decreases in the supply of trophic or tropic factors from supporting cells, are often suggested as underlying causes, but there have only been a few direct analyses of age-related axon regeneration.
Our aim has been to directly observe regenerating axons as they grow and ultimately reoccupy denervated neuromuscular synaptic sites in order to learn what changes in this process are age-related. We have accomplished this by *in vivo* imaging of transgenic mice that express fluorescent proteins in their axons using a custom video-rate 2-photon microscope in order to obtain high spatiotemporal resolution time-lapse images of growing axons in living animals. The results show that axon growth in aged animals is more saltatory than in younger animals. The growth rate is impaired by frequent halting associated with axonal bulging suggesting that the intracellular transport rate is faster than axon extension leading to temporary increases in volume. In addition axons show more extensive branching within the fasciculated nerve bundle. Immuno-staining for myelin debris indicated that more uncleared axonal debris was present in the Schwann cells within old damaged nerves than in younger ones suggesting that delayed

debris clearance by glia or other cells may be hindering the advance of growing axon tips by mechanically blocking the passage in the closed Schwann cell tubes. Direct visualization of aged axons shows them attempting to navigate around the debris-containing cells. Our data imply that facilitating clearance of axon debris might be a good target for treatment of nerve injury in the aged.

Title: Protective effect of curcumin on behavioral and morphological alterations induced in a model of striatal degeneration in rats

Authors: *R. A. SANTANA MARTINEZ[1], J. PEDRAZA-CHAVERRÍ[2], A. SANTAMARIA[1], P. D. MALDONADO[1]
[1]Natl. Inst. of Neurol. and Neurosurg., Mexico, Mexico; [2]Natl. Autonomous Univ. of Mexico, Mexico, Mexico

Abstract: Quinolinic acid (QUIN), an endogenous competitive agonist of NMDAr, is considered an excitotoxin, and its intrastriatal administration to rats has been used to reproduce some biochemical, behavioral and morphological alterations similar to those observed in some neurodegenerative disorders. QUIN induces selective neuronal death in the striatum due to overactivation of NMDAr (excitotoxicity), which has been related to acute oxidative stress. Curcumin (CUR) is a major polyphenol derived from the rhizome *Curcuma longa* and its biological properties as direct (free radical scavenger) and indirect (Nrf2 inducer) antioxidant are well known. Additionally, CUR is highly lipophilic and is able to reach the brain. In this context, we studied the protective effects of CUR in a neurodegenerative model produced by QUIN in rats.
Animals intrastriatally infused with QUIN (240 nmol/µl) received CUR (400 mg/kg, i.g.) daily during 6 consecutive days, and on day seven, animals were euthanized to evaluate histological changes by hematoxylin & eosin staining. The behavioral study was assessed by the limb-use asymmetry test at day -1 (one day before QUIN microinjection), as well as on days 2 and 6 after QUIN injection. In this test, we estimated the number of contacts the animals on the walls using

the ipsilesional (affected limb), the contralesional (unaffected limb), and both limbs simultaneously. CUR treatment significantly decreased the QUIN-induced striatal morphological alterations by reducing the number of lesioned cells. CUR administration also partially recovered the ability of QUIN-lesioned animals to use both limbs, while decreased the single use of the ipsilesional limb (20 % below the QUIN condition). Our results suggest that CUR treatment may constitute an effective therapeutic tool to ameliorate some features of neurodegenerative events in which the optimal maintenance of the redox status is crucial for neuronal survival. Further studies are needed to elucidate the precise mechanism of CUR actions and to explain the protective effect observed in the toxic paradigm induced by QUIN.

Title: Systematic review of thiazolidinediones (TZDs) in pre-clinical studies reveals beneficial effects on cognition

Authors: *S. P. MURPHY[1], C. L. GIBSON[2], A. N. MURPHY[3]
[1]Neurolog. Surgery, Univ. Washington Schl Med., SEATTLE, WA; [2]Univ. of Leicester, Leicester, United Kingdom; [3]Pharmacol., UC San Diego, San Diego, CA

Abstract: Used in the treatment of Type 2 diabetes, thiazolidinediones (TZDs) are insulin sensitizers that normalize blood glucose and lipid levels, improve metabolic flexibility, and have anti-inflammatory activity. A member of this drug class, pioglitazone, is in clinical trials for multiple neurological indications, including Alzheimer's and Parkinson's Diseases, and stroke, while similar trials of rosiglitazone have been halted due to concerns over increased risk of adverse cardiovascular events. Using meta-analysis, we have assessed the potential benefits of pioglitazone and rosiglitazone on cognitive function in preclinical studies across a variety of

models, including those for Alzheimer's and Parkinson's Diseases, aging, traumatic brain injury, cerebral ischemia, diabetes, epilepsy, and chemical-induced amnesia and vascular dementia. Analysis of the 24 studies we identified has revealed an overall neuroprotective effect of TZDs, with significant improvement of cognitive function by both pioglitazone and rosiglitazone. Evaluation of study quality raised some concern that higher quality studies reported less benefit. Interestingly, efficacy was similar whether TZDs were administered either acutely or chronically, and there appeared to be less of an effect in 'control' animals. Overall, the animal studies thus far suggest a beneficial effect of TZDs on cognitive function, and we await the results of human trials in order to evaluate how well these preclinical models predict efficacy.

Title: Derivation of scalable, NURR1 expressing dopaminergic progenitor cells from human embryonic stem cells

Authors: *J. M. CHILTON[1], K. L. GALLAND[2], J. A. MCCABE[3], S. L. STICE[3]
[1]Aruna Biomedical, Inc., Athens, GA; [2]ArunA Biomedical, Inc., Athens, GA; [3]Univ. of Georgia, Athens, GA

Abstract: Parkinson's disease (PD) is one of the most common neurodegenerative diseases affecting approximately 1-2% of the population over 65 years of age. The lack of an appropriate cell type that can be expanded for high throughput drug screening has hindered progress in PD drug discovery, as well as investigating disease mechanisms underlying PD. Our goal was to generate human dopaminergic progenitor cells, derived from human embryonic stem cells (hESCs), which are homogeneous, expandable and demonstrate a propensity for dopaminergic differentiation. We isolated neural progenitor-like cells that exhibited greater than 95% immunoreactivity for nuclear receptor related 1 protein (NURR1 or NR4A2), a transcription factor essential for the generation of midbrain dopaminergic neurons, and we refer to these cells as DopaPro™ cells. DopaPro™ cells displayed normal karyotype, formed adherent monolayers and were proliferative over multiple passages, allowing for high throughput screening (HTS) scale production and dopaminergic differentiation. To determine if these cells could generate

dopaminergic neurons, DopaPro™ cells were differentiated in the presence of leukemia inhibitory factor (LIF), brain derived neurotrophic factor (BDNF), glial derived neurotrophic factor (GDNF), transforming growth factor beta 3 (TGF-β3), forskolin and ascorbic acid (AA). By 3 weeks, approximately 10% of differentiated DopaPro™ cells showed immunoreactivity for tyrosine hydroxylase (TH). In addition, since the DopaPro™ cells are putative midbrain progenitor cells, we asked whether these cells required regionalization signals such as Sonic Hedgehog (SHH) or fibroblast growth factor 8 (FGF8), which are normally used in directed differentiation of hESCs to dopaminergic neurons. The DopaPro™ cells did not require, nor was their differentiation to TH expressing populations significantly enhanced, when cultures were exposed to SHH and FGF8 for 2 weeks prior to culture in LIF, BDNF, GDNF, TGF-β3, forskolin and AA. Both control and SHH/FGF8 treated populations contained approximately 10% dopaminergic neurons. Here, hESC-derived progenitor cells poised for differentiation into TH expressing populations and potentially dopaminergic cell derivation were generated, thus reducing time and need for midbrain induction factors. Our results show our DopaPro™ cells are a unique, renewable and scalable cell source for PD research.

Title: Evaluation of biomaterials for the release of chemotropic proteins into the brain.

Authors: A. RIOS RAMIREZ[1], *M. GIORDANO[2], E. TAMARIZ[3]
[1]Cognitive and Behavioral Neurobio., Univ. Nacional Autónoma De México, Querétaro,

Querétaro., Mexico; [2]Cognitive and Behavioral Neurobio., Univ. Nacional Autónoma De México, Querétaro, Qro., Mexico; [3]Biomedicine, Univ. Veracruzana, Xalapa, Veracruz, Mexico

Abstract: Protein release into the central nervous system is restricted by the presence of the blood brain barrier. One potential strategy is the release of substances of interest into the central nervous system by the use biomaterials that should be biocompatible, and biodegradable. Also, the products of biodegradation should not be neurotoxic. In particular, biomaterials could be used for site-specific delivery of proteins with chemotropic properties, to form concentration gradients and to stimulate and direct axonal growth of implanted cells, for example in models of Parkinson's disease, promoting proper reinnervation and restoration of the nigro-striatal pathway. In this study two biomaterials were evaluated, methylcellulose hydrogels and microspheres of a copolymer of lactic acid-glycolic acid (PLGA) wherein was encapsulated recombinant semaphorin 3A (sema 3A-Fc). This protein has an attractive effect on dopaminergic ventral midbrain neurons (VM) during the formation of the nigro-striatal pathway and repellent in dorsal root ganglion neurons (DRG) during embryonic development. In vitro tests showed that the encapsulation and release of proteins in PLGA microspheres is of low efficiency and no concentration gradient is formed, as compared with methylcellulose hydrogels (MCH). Evaluation of the biological effect of released Sema 3A-Fc in primary cultures of VM and DRG showed that the chemotropic protein is efficiently released from MCH and retains its functionality. We observed increased growth of VM dopaminergic axons compared with control; in contrast, in primary cultures of DRG retraction of axons near the Sema3A-Fc source was detected. These results indicate that MHC may be used for continual release of proteins into the brain. Furthermore behavioral tests in rats unilaterally implanted with MCH in the striatum at 1 week, 15 days and 1 month post-transplantation showed no alterations in locomotor activity and other behavioral tests. The results so far indicate that MCH could be used to release chemotropic proteins into the brain in a controlled way, without inducing neurological or behavioral alterations. It must be noted that it is also important to verify that this vehicle does not cause an inflammatory reaction after implantation into the brain.

Title: CaMKIV reduction may contribute to age-related adult neurogenesis reduction

Authors: *S. MIYAKE[1], N. WALTON[1], A. NAGAKURA[2], Y. SHITAKA[2], A. MIYAKE[2], K. NI[2], N. MATSUOKA[2], C. HEUSNER[1], J. KOGAN[1], Q. CHEN[1], R. SHIN[1], A. GROSS[1], K. TAJINDA[2], K. TAMURA[1], M. MATSUMOTO[1]

Abstract: Age-related memory impairment is a common occurrence in many mammalian species. Previous work suggests that the hippocampus, a brain region strongly implicated in the formation and retrieval of memories, is often impaired with age. Interestingly, a marked, age-associated decline in hippocampal adult neurogenesis has been described in rodents and primates, including humans. These declines in neurogenesis have been hypothesized to be related to hippocampal function, however the mechanism(s) for this decline have not yet been fully elucidated.
Here, we show that a significant reduction in expression of pCaMKIV(T196) and total-CaMKIV occurs in the hippocampus of aged rats compared to younger controls. Reduction of total CaMKIV is evident at 19 months and 25 months of age. A significant reduction in pCaMKIV is only observed at 25 months of age. To determine if CaMKIV expression is related to changes in adult neurogenesis, we examined CaMKIV expression in the dentate gyrus (DG) of CaMKIIa hKO mice, which exhibit increased hippocampal adult neurogenesis. CaMKIV mRNA in the DG is significantly increased in CaMKIIa hKO mice compared with age-matched WT mice, suggesting a role for CaMKIV in hippocampal adult neurogenesis. Additionally, CaMKIV mRNA is strongly upregulated following the terminal differentiation adult hippocampal neural stem cells.
These data suggest that CaMKIV may be positively correlated with neurogenesis and CaMKIV reduction may be one cause of the observed decline in age-related adult neurogenesis.

Title: The effects of aging on dendritic spine density and morphology in macaque dorsolateral prefrontal and primary visual cortices

Authors: *M. E. BAILEY, D. T. OHM, D. DUMITRIU, J. H. MORRISON
Mount Sinai Sch. of Med., New York, NY

Abstract: Previous results from our lab indicate that aging decreases both spine density and the proportion of small, thin spines in layer III neurons of the dorsolateral prefrontal cortex of rhesus monkeys.
In the present study, we used intracellular injection of Lucifer Yellow dye and 3D confocal microscopy to compare the effects of aging on dendritic spine density and morphology in the dorsolateral prefrontal cortex and primary visual cortex. A cohort of behaviorally-characterized rhesus monkeys ranging in age from 9 to 33 years was used for this analysis. Dendritic spine density, head diameter, and head volume were measured in order to evaluate the effect of aging on spine architecture.
Our results confirm that pyramidal neuronal spine density decreases with age in the prefrontal cortex, but not in primary visual cortex. Additionally, thinner spines make up a larger proportion of the total population in young animals in both cortical areas, though this effect is more pronounced in the prefrontal cortex. Further analysis will examine the relationship between performance on the delayed response and delayed nonmatching to sample tasks and spine density and morphology in both regions.

Title: Age-dependent effects on neuroblasts in the rostral migratory stream

Authors: *A. S. MOBLEY[1], A. BRYANT[1], M. B. RICHARD[3,4], J. H. BRANN[5], S. J. FIRESTEIN[5], C. A. GREER[1,2]
[1]Neurosurg., Yale Univ., NEW HAVEN, CT; [2]Neurobio., Yale Univ., New haven, CT; [3]Lyon Neurosci. Res. Ctr., INSERM, Lyon, France; [4]Univ. of Lyon, Lyon, France; [5]Biol. Sci., Columbia Univ., New York, NY

Abstract: Throughout life the subventricular zone (SVZ) is a source of new olfactory bulb (OB) interneurons. Neuroblasts born in the SVZ migrate to the OB tangentially in chains through an astrocyte restricted route, the rostral migratory stream (RMS)[1]. In mice the RMS is ~5 mm long with a pervasive vasculature which may aid migration; neuroblasts take 10-14 days to reach the OB from the SVZ[2]. During migration neuroblasts retain the ability to divide. Upon arrival in the OB neuroblasts migrate radially to the granule and glomerular layers and differentiate into granule and subpopulations of periglomerular (PG) cells that integrate into synaptic circuits. SVZ neurogenesis decreases with age, and is suggested as a factor in age-related olfactory deficits[3]. How the decrease in SVZ neurogenesis may translate into neuroblast migration, proliferation within the RMS, and the differentiation of interneuron subpopulations is less well understood. To address these issues we injected 6, 12, 18 and 23 month old mice with BrdU and sacrificed them at different intervals. We divided the RMS analyses into three regions, the vertical arm (VA) that extends from the SVZ and descends beneath the corpus callosum, the elbow, composed of the rostral curve towards the OB at the base of the VA, and the horizontal arm (HA), the final rostral extension into the OB. PG cell subpopulations were quantified within defined regions of the OB. Our data extends the finding that neuroblasts continue to proliferate in the RMS. Proliferation in the VA decreased during aging, similar to the SVZ, while proliferation in the elbow and HA remained stable. Further, we found that aging affects RMS size in a regional manner due to decreased numbers of neuroblasts, with no effect on the vascular or glial surround. The rate of neuroblast migration remained stable with age; 14 days after BrdU injection there were no significant differences in BrdU+ cells in the RMS across ages. While the number of newborn PG cells decreases with age, the population numbers and their distribution remain stable, consistent with our previous data[4]. These data suggest that despite a decrease in neurogenesis and changes in RMS organization cellular populations in the OB remain largely stable during aging, with implications for olfactory-related behavior.

Title: Neural stem cells and hydrogels: Enhancing neural tissue engineering potential

Authors: *E. R. AURAND[1], J. WAGNER[2], C. LANNING[2], K. B. BJUGSTAD[3]
[1]Neurosci. Program, [2]Bioengineering, [3]Pediatrics, Univ. of Colorado - Anschutz Med. Campus, Aurora, CO

Abstract: Neural tissue engineering could greatly benefit from the use of hydrogels; however, the hydrogels must be customizable and, ideally, mimic the various properties of brain tissue in addition to being therapeutically functional. Currently, hydrogels used for neural tissue engineering are not thoroughly characterized for their chemical, physical, and mechanical properties. The goal of this research was to create a well-characterized hydrogel using commercially available materials suitable for the implantation of neural stem cells. Hydrogels were created from a range of ratios of hyaluronic acid (HA) to poly(ethylene glycol) (PEG). These hydrogels were assessed for the physical properties of polymerization and degradation, the mechanical property of compressive modulus, and the cytocompatibility with encapsulated neural stem cells. The polymerization and degradation rates of the HA:PEG hydrogels were a function of the amount of HA incorporated into the hydrogel. With increasing amounts of HA, the rate of polymerization increased (>120 min to <2 min); conversely, with increasing HA content, there was a decrease in the rate of degradation (<12 hr to >10 d). The compressive modulus was also a function of the HA content. Compressive modulus (hydrogel stiffness) increased with increasing HA content and ranged from 0.1 to 32kPa (rodent brain tissue ranges

from 2-10kPa). In addition to physical and mechanical characterization, neural stem cells derived from fetal rats (fNSC) were encapsulated within a three-dimensional (3D) HA:PEG hydrogel environment. Twenty-four hours post-encapsulation, cell survival was measured and compared to cells plated on standard tissue culture plates (TCP; controls). Results demonstrated that 3D cultures typically had good survival/proliferation, with an average survival rate of 122.51±2.69% compared to only 34.62±3.47% in TCP controls. fNSC survival was found to be dependent on the relative proportion of HA or PEG. At low concentrations of PEG, fNSC survival was high, regardless of HA content. At high concentrations of PEG, fNSC survival was dependent on the amount of HA, with greater survival at higher HA concentrations. These results indicate that there can be a wide range of HA:PEG-based hydrogels which are compatible with neural stem cells. Furthermore, the physical and mechanical properties can be readily altered by changing the proportion of HA without substantially altering neural stem cell survival. This bodes well for neural tissue engineering strategies, allowing for the possibility to create customized hydrogels for specific applications.

Title: Molecular pathogenesis of a central diabetes insipidus rat strain

Authors: *T. ITO, N. TAKEUCHI, K. YOSHIDA, K. YUKAWA
Physiol., Meijo Univ., Nagoya / Aichi, Japan

Abstract: As previously reported, our animal facility maintains a Wistar rat strain showing polydipsia and polyuria. The rat strain offspring gain the pathologic phenotype in an autosomal recessive manner. Significantly lower urine osmotic pressure and plasma arginine vasopressin (AVP) level of the rat strain indicated diabetes insipidus as the primary cause of the symptom. Sequence analysis of the preprovasopressin (preproAVP) mRNA did not reveal any mutations in the nucleotide sequences. Real-time PCR analysis of vasopressin mRNA did not detect any significant differences in the vasopressin mRNA level in supraoptic and paraventricular nuclei of the hypothalamus between the diabetes insipidus strain and the normal Wistar rat. Subdermal injection of AVP analog (dDAVP, 0.4μg/Kg) to the strain could maintain both high urine osmolality and decreased urine volume as longs as dDAVP remained at the effective levels,

which demonstrated normal water reabsorption system in the kidney. To examine if lower plasma AVP level of the strain results from either the decrease of AVP axonal transport in hypothalamic neurons or disturbed AVP secretion from axon terminals into blood, we quantified the expression level of AVP in the hypothalamus and pituitary from both the diabetes insipidus strain and the normal Wistar rat by immunohistochemistry and western blotting. Immunohistochemical studies showed higher AVP level in hypothalamic nuclei and pituitary of the diabetes insipidus strain as compared with the normal Wistar rat, suggesting a defect of AVP secretion from the posterior lobe of puituitary in the central diabetes insipidus rat strain.

Title: Subtle Impact of the reduction in dopamine transporter (DAT) gene expression in DAT-Cre mice

Authors: S. MINGOTE[1], M. O. CHOHAN[2], N. CHUHMA[1], C. GELLMAN[1], B. INBAR[2], S. RAYPORT[1], *H. M. MOORE[2]
[1]Psychiatry and Mol. Therapeut., Columbia Univ. and New York State Psychiatric Inst., New York, NY; [2]Psychiatry and Integrative Neurosci., Columbia Univ. and New York State Psychiatric Inst., NEW YORK, NY

Abstract: DAT-Cre knock in mice, with a heterozygous insertion of the Cre allele in the dopamine transporter (DAT) locus (Zhuang et al., 2005) have been widely used for conditional targeting strategies in DA neurons. We have found that DAT expression in DAT-Cre mice, backcrossed onto a congenic C57/BL6 background at P60, is 64% of wt DAT levels (see Figure), as compared to DAT hemizygous mice that have 36% of wt DAT levels (Giros et al., 1996). There were no significant changes in tyrosine hydroxylase, VMAT, dopamine D1 or D2 receptor expression in either the ventral midbrain or the striatum of DAT-Cre mice; GAD expression was slightly increased in the ventral midbrain. There was no significant change in DA content in the nucleus accumbens or dorsolateral striatum, but there was a significant reduction in prefrontal cortex. Decreases in DA content were accompanied by increases in the ratio of homovanillic acid to DA, consistent with a reduction in intracellular DA but increased levels and metabolism of

extracellular DA. In ventral midbrain slices from DAT-Cre mice, there were no significant differences in the intrinsic properties of DA neurons, or in their firing patterns. The firing characteristics of DA neurons in vivo, assessed by extracellular single-unit recordings of electrophysiologically identified DA neurons under chloral hydrate anesthesia, were unchanged in our preliminary analyses. In contrast to DAT-Cre mice, DAT-IRES-Cre mice (Bäckman et al., 2006) show no significant impact on DAT gene expression, or in the other DA system genes. Thus, the DAT-Cre allele, but not the DAT-IRES-Cre allele, significantly compromises DAT expression and produces subtle changes that should be considered in the interpretation of the apparent effects of conditional deletion of target genes in DA neurons in DAT-Cre mice.

Title: Activity-based anorexia reduced cell proliferation in the ventral hippocampus of adolescent female rats: Do changes remain following recovery and relapse?

Authors: *N. S. BURGHARDT[1], K. LAURINO[2], R. HEN[1], N. BARBARICH-MARSTELLER[2]
[1]Dept Neurosci, Psych & Pharmacol, Columbia Univ., NEW YORK, NY; [2]Dept. of Psychiatry, Col. of Physicians and Surgeons, Columbia Univ., New York, NY

Abstract: Anorexia nervosa is a psychiatric disorder that is characterized by severe self-starvation and life-threatening weight loss. The predominately female disorder typically develops during adolescence and is often associated with compulsive exercise and anxiety. Aspects of anorexia nervosa can be modeled in animals using a translational approach known as activity-based anorexia (ABA), which combines limited access to food with unlimited access to a running wheel. Under these conditions, rodents run continuously, even throughout the daily hour of food access, thereby promoting self-starvation. This failure to adapt food intake to increasing energy demands leads to significant weight loss and possible death. ABA in rats induces changes in GABA receptor subunits and decreases gliogenesis in the hippocampus, a structure known to play an important role in regulating anxiety. Here, we used adolescent female rats to investigate the effects of ABA on the generation of new neurons in the dentate gyrus of the hippocampus. Neurogenesis was evaluated following three time points: 4 days of ABA (ABA), 7 days of recovery from ABA (Recovery), and 4 days of a second exposure to ABA after recovery (Relapse). At each time point, four groups of rats were tested: control (24 h/day food access), food-restricted control (1 hr/day food access), exercise (24 h/day food and wheel access), and ABA (1 h/day food access, 24 h/day wheel access). Rats were injected once with 5-bromo-2'-deoxyuridine (BrdU) (200 mg/kg, i.p.) and perfused two hours later so that the effects of ABA, recovery, and relapse on cell proliferation could be evaluated. BrdU-positive (+) cells were quantified throughout the rostro-caudal extent of the granule cell layer of the dentate gyrus. As expected, the ABA group dramatically increased running wheel activity, leading to a decrease in body weight with each day of food restriction. Four days of ABA led to a significant decrease in BrdU+ cells (40%) in the ventral but not dorsal hippocampus. ABA was also associated with significantly fewer BrdU+ cells in regions outside of the granule cell layer, confirming that ABA decreases gliogenesis. Ongoing analyses will determine the extent to which the decrease in BrdU+ cells in the ventral dentate gyrus represents reduced neurogenesis rather than reduced gliogenesis. We will also evaluate the independent effects of exercise and food restriction on cell proliferation in the control groups and explore whether alterations in cell proliferation remain following recovery and relapse. Our results indicate that the ventral hippocampus is sensitive to stress induced by ABA.

Title: Global 30% maternal nutrient reduction (MNR) from 0.16 to 0.9 of gestation (G) decreases leptin receptor (Ob-R) protein expression in the fetal baboon hypothalamic arcuate (ARC) and paraventricular nuclei (PVN)

Authors: *C. LI, P. W. NATHANIELSZ, T. J. MCDONALD
OB/GYN, Univ. Texas Hlth. Sci. Ctr, San Antonio, San Antonio, TX

Abstract: INTRODUCTION: In human pregnancy the adipose hormone leptin is increased in diabetic pregnancy and pre-eclampsia and reduced in maternal and fetal plasma in intrauterine growth restriction (IUGR; Placenta 23:103). Leptin has many central nervous system functions including signaling to inhibit appetite. The ARC and PVN are recognized as critical appetite regulatory nuclei producing neuropeptides that control feeding behavior and energy balance. We previously showed that MNR: 1) increases protein expression of fetal baboon ARC and PVN orexigenic peptides, 2) decreases anorexigenic peptides and 3) decreases placental leptin and Ob-R by 0.9G. In the present study, we hypothesized that MNR regulates Ob-R protein expression in both the ARC and PVN at 0.9G. **METHODS:** Pregnant baboons were fed a *ad lib* controls (CTR; n=7) or 70% CTR global diet (MNR; n= 6) from 0.16 to 0.9G and fetuses ecovered at CSsection with general anesthesia. Ob-R protein expression was determined by immunohistochemistry with Ob-R antibody (Santa Cruz, sc-1833) and quantified by image analysis (ImageJ, NIH) for density (arbitrary density units and fraction (area immunostained/-area of field x 100%). Analysis, Student's t-test, set at 0.05; data = mean ± SUM. RESULTS:

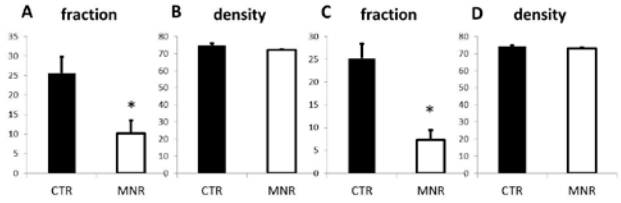

Figure 1. Fetal baboon hypothalamic leptin receptor immunoreactivity in arcuate (A & B) and paraventricular nuclei (C & D) CTR n=7, MNR n=6. Data =mean ± SEM. *$p < 0.05$.

CONCLUSIONS: The observed decrease in OB-R in the appetitive centers would decrease the efficiency of leptin negative feedback on appetite. If this change persists post-natally it could contribute the predisposition to postnatal obesity and accompanying pathologies associated with IUGR.

Title: Dopaminergic alterations related with impairment of work memory in a perinatal asphyxia model.

Authors: *S. J. LOPEZ-PEREZ, A. MORALES-VILLAGRÁN
Mol. and Cell. Biol., Univ. of Guadalajara, Zapopan, Jalisco, Mexico

Abstract: Perinatal asphyxia is a process that produce neurotoxic milieu in the brain, by an initial glutamate accumulation in the extracellular space. This represents a potential risk of permanent brain damage, with high probability to develop
important neurological sequelae like learning and memory disabilities. Both these capacities are integrated in the frontal cortex (FC) and are related directly with dopaminergic neurotransmission in the striatum (ST). The aim of this work
was to analyze the response of dopaminergic D1 and D2 receptors and dopaminergic transporter in striatum and frontal cortex of juvenile Wistar rats (30 days old) subjected to 45 min of asphyxia in early postnatal period (11 days old). We also evaluate the work memory, related with the frontal circuits, in the asphyxiated animals, through a standard object recognition test. 11 days old pup rats were subjected to an asphyxia protocol in a sealed chamber, fill with a mixture of 8% O_2 and 92% N_2 for a period of 45 min. At 30 postnatal days, asphyxia and controls animals were selected to one of the next experimental procedures: 1) Animals were sacrificed to obtain the brains and dissected the FC and ST. Tissues were homogenate and centrifuged and final supernatants were assayed to DA and DOPAC content by HPLC. 2) Animals were sacrificed to obtain the brains and dissected the FC and ST. Tissues were homogenate and
centrifuged and final supernatants were assay to total protein concentration. Aliquots containing 80 µg of total protein were tested to D1/D2 receptors and dopaminergic transporter (DAT) in each region, by Western blot. 3) Finally, a third group of animals, formed by asphyxiated and control animals, were used to carry out a standard object recognition test. Results from total DA and DOPAC quantification shows a generalized decrease in the DA content in FC and ST, while DOPAC show no changes in FC and low level in ST. Regarding to D1, D2 and DAT protein expression, it was observed an increase in the expression of D2 receptor and DAT, with no changes in expression of D1 receptor. The object recognition test allowed us to observe that asphyxiated animals fail in the recognition of an object that previously has been explored by

them. These results suggest alterations in the dopaminergic neurotransmission in ST and FC, which could be generating a neurochemical substrate to failures in the work memory task.

Title: The effects of fourth ventricle intraventricular hemorrhage on the development of the postnatal mouse cerebellum

Authors: J. YOO, G. MAK, *D. GOLDOWITZ
Med. Genetics; U of BC, Ctr. for Mol. Med. & Ther., Vancouver, BC, Canada

Abstract: Intraventricular hemorrhage (IVH) is the most common neurological problem in premature infants and often leads to neurological sequelae, such as cerebral palsy, post-hemorrhagic hydrocephalus, and cognitive dysfunction. With the increase in survival of preterm infants and the improvement in neuroimaging technology, the detection of IVH in the fourth ventricle of preterm infants is becoming increasingly common. The cerebellum, which is involved in motor control, motor learning and cognition, is positioned immediately above the fourth ventricle, but how fourth ventricle IVH affects the development and function of cerebellum remains largely unknown. Therefore, our study focuses on developing a mouse model of fourth ventricle IVH to determine the anatomical and behavioural phenotypes resulting from the hemorrhage and to understand the mechanisms of injury in the neonatal cerebellum. To induce a hemorrhage in the germinal matrix of the cerebellum, we injected collagenase, which breaks down surrounding blood vessel walls, into the fourth ventricle of postnatal (P) day 2 mice. Controls were injected with saline. We then analyzed cell proliferation, apoptosis, and inflammation in the developing cerebellum. Also, we performed various histological assessments to detect any changes in size of cerebellum and the number of cerebellar cell types, including granule cell, Purkinje cell, interneuron, and oligodendrocyte. Behavioral analyses were also conducted on P60 mice to assess locomotor and cognitive abilities. In our model of fourth ventricle IVH, we found a delay in cerebellar development, reduction in granule cell number, and persistent neurobehavioral abnormalities similar to premature infants with IVH. Therefore, our study provides a novel pre-clinical model of IVH that can be used to understand the

pathophysiology of the disease, as well as for the development and evaluation of preventive therapies and post-hemorrhagic treatments.

Title: Perinatal asphyxia and fetal asphyctic preconditioning: Global inflammatory impact on brain cortex, cerebellum and liver

Authors: *E. VLASSAKS[1,2], J. S. H. VLES[3], T. BRUDEK[4], E. STRACKX[1,2], H. W. STEINBUSCH[1], B. W. KRAMER[2], B. PAKKENBERG[4], D. A. W. GAVILANES[2]
[1]Mental Hlth. and Neurosci., Maastricht Univ., Maastricht, Netherlands; [2]Neonatology, [3]Child Neurol., Maastricht Univ. Med. Ctr., Maastricht, Netherlands; [4]Res. Lab. for Stereology and Neurosci., Bispebjerg Univ. Hosp., Copenhagen, Denmark

Abstract: Background:
Fetal and perinatal asphyxia are the major cause of neonatal mortality and morbidity worldwide. During periods of moderate and severe asphyxia (hypoxia-ischemia), fetuses develop multi-organ failure with involvement of many vital organs such as heart, kidneys, liver and brain.
Objectives:
1. To investigate inflammatory changes after fetal and perinatal asphyxia in brain cortex, cerebellum and liver.
2. To investigate if the combination of both insults (preconditioning) would have any hepatic or neuroprotective effect.
Methods:
In pregnant rats, fetal asphyxia was induced at E17 by clamping the uterine circulation for 30 min. Perinatal asphyxia was induced at E21/22 by submersing the uterine horns in a saline bath (37ºC) for 19 min. At different time points after both insults, we assessed inflammatory changes by means of quantitative RT-PCR and immunohistochemistry in brain cortex, cerebellum (results are pending) and liver.
Results:
Fetal asphyxia induced down regulation of the acute brain cytokine response with decreased IL-1β, TNF-α and IL-10 mRNA levels. However, IL-6 mRNA levels increased 96 h after fetal

asphyxia compared to controls. After birth, we found increased IL-10 and IL-6 mRNA expression after severe perinatal asphyxia, though this increase was not present in newborns that were previously exposed to fetal asphyctic preconditioning. Opposite effects were found in the liver, where we examined increased levels in IL-1β, IL-6 and IL-10 mRNA after fetal asphyxia. Postnatal IL-6 mRNA expression increased after perinatal asphyxia and was comparable with baseline levels in neonates that were previously exposed to fetal asphyctic preconditioning.
Conclusion:
In the brain cortex, fetal asphyctic preconditioning leads to down regulation of the acute inflammatory response, while the systemic response in the liver was reversed. This modulation of the cytokine response probably results in a protective phenotype postnatally. Therefore, elucidating the inflammatory pathways involved in asphyxia and preconditioning may have significant implications for preventing post-asphyctic multi-organ failure.

Title: A behavioral assessment of sex differences in a mouse model of severe neuronal migration anomalies

Authors: *D. T. TRUONG[1], C. E. SZALKOWSKI[1], G. D. ROSEN[2], R. H. FITCH[1]
[1]Behavioral Neurosci., Univ. of Connecticut, Storrs, CT; [2]Neurol., Harvard Med. Sch., Boston, MA

Abstract: Neuronal migration anomalies have been linked to a wide range of neurobehavioral and cognitive disorders including epilepsy, autism, and developmental language and reading disabilities. Moreover, researchers have suggested that underlying dysfunction in rapid auditory processing (RAP) may contribute to the etiology of developmental language/learning impairments. As such, rodent models have been used as an invaluable tool to study the link between neuronal migration anomalies and auditory processing ability. These studies have found RAP deficits in rodents with spontaneous, genetically manipulated, and injury-induced cortical

anomalies. Such results suggest a link between neuronal migration disruption and RAP, and further provide one possible underlying biological and behavioral etiology for language related dysfunction in clinical populations. Interestingly, males are more commonly diagnosed with neurodevelopmental disorders associated with language learning impairments, and research using rodent models of disrupted neuronal migration has also revealed sex differences in RAP, with affected males typically performing worse than affected females.
The current study was designed to examine possible sex differences in behavioral measures (RAP, Morris spatial water maze, non-spatial water maze) using a recently discovered model of spontaneously occurring severe neuronal migration disruption (bilateral subcortical nodular heterotopia and callosal agenesis) in a BXD29 recombinant inbred strain of mice (BXD29-Tlr4^{lps-2J}/J). Current results replicate our previous behavioral findings, with affected male mice showing a specific impairment in rapid auditory processing in comparison to the isogenic BXD29/Ty mice (no cortical anomaly). Interestingly, comparable deficits were also seen in affected females (indicating a lack of sex differeneces). Overall, these data suggest that the severity of the neuronal migration anomaly in BXD29-Tlr4^{lps-2J}/J mice impairs auditory processing in both sexes. The current findings provide insight to the neurodevelopmental anomalies that may mediate underlying emergent impairments of language-related processing in humans by providing a model wherein both sexes appear to be affected equally (consistent with clinical evidence that despite much smaller numbers, females are also affected with language/learning disorders).

Genet., [9]Pediatrics, [10]Microbiology&Immunology, IU Sch. of Med., Indianapolis, IN; [11]Chem., [12]METACyt Biochem. Analysis Ctr., Indiana Univ., Bloomington, IN

Abstract: Neurofibromatosis type 1 (NF1) is an autosomal dominant disease with mutation in one copy of the NF1 gene (NF1+/-) that affects roughly 1 in 3500 individuals, and frequently presents with learning disabilities, attention deficit hyperactivity disorder, and social deficits similar to autism spectrum disorders (ASDs). The NF1 gene encodes neurofibromin, a cytoplasmic GAP-like protein that is expressed throughout the central nervous system. Previously, we demonstrated that Nf1-deficient (Nf1+/-) mice show social learning deficits, express greater activation of MAPK pathway following growth factor stimulation, which were rescued by deleting Pak1 gene activity (Nf1+/-/Pak1-/- mice). We also showed that projection neurons in basolateral amygdala (BLA) region in Nf1+/- mice exhibit increased frequency (but normal amplitude) of miniature inhibitory post-synaptic currents (mIPSCs). Here, we further characterized the mechanisms of social learning deficits in Nf1+/- mice. We confirmed that compared to WT, the Nf1+/- mice demonstrate selective deficit only in social learning but not in elevated-plus maze avoidance learning, olfactory habituation, novel object recognition or passive avoidance tests. Using the whole-cell patch clamp technique, we also determined that deletion of Nf1 gene decreases long-term potentiation (LTP) in the amygdala. Interestingly, we also observed a significant increase in amplitude of miniature excitatory post-synaptic currents (mEPSCs) in Nf1+/-/Pak1-/- and Pak1-/- mice. Utilizing mass spectrometry, we measured expression levels of 338 proteins in amygdala region in WT, Nf1+/-, Nf1+/-/Pak1-/- and Pak1-/- mice. Our plan was to specifically identify proteins that were changed in Nf1+/-, compared to WT, and those that were restored in Nf1+/-/Pak1-/- mice but were not similarly altered by deletion of Pak1 gene alone. Using INGENUITY pathway analysis software, we identified reduction in several key proteins (ADAM22, CAP1 and HSP70) associated with glutamate neurotransmission and synaptic plasticity in the amygdala. We further confirmed loss of ADAM22 in the amygdala region with immunohistochemical analysis. In conclusion, our findings demonstrate that Nf1+/- mice express a selective deficit in social learning that is seen in Nf1+/- mice and rescued in Nf1+/-/Pak1-/- mice appears to involve disruption of GABA-mediated inhibition and glutamate excitation of the projection neurons of the amygdala, perhaps resulting from altered expression of important synaptic proteins such as ADAM22 in the amygdala.

Title: Neuronal activation following social challenge in adolescent Grin1 knockdown mice

Authors: N. V. RIDDICK[1], V. D. NIKOLOVA[1], K. L. AGSTER[1], L. K. BAKER[1], B. H. KOLLER[2], G. E. DUNCAN[1], *S. S. MOY[1]
[1]Psychiatry, [2]Genet., Univ. NC Sch. Med., CHAPEL HILL, NC

Abstract: Genetically-altered mice with reductions in the NR1 subunit of the *N*-methyl-D-aspartate (NMDA) receptor, encoded by *Grin1*, have been proposed as a model for aberrant glutamatergic neurotransmission and behavioral phenotypes in schizophrenia and autism. *Grin1* knockdown mice recapitulate impaired social behavior, cognitive deficits, and other features of severe neuropsychiatric disorders, and also show deficient neuronal activation, measured by induction of Fos protein, following a social challenge. However, most abnormal phenotypes have been observed in adult mice. We have recently reported that, in contrast to a marked lack of sociability in adulthood, *Grin1* knockdown mice have significant hypersociability during adolescence. The present study examined Fos induction in several brain regions of adolescent (postnatal day 30-35) male and female *Grin1* and wild type mice following a modified resident/intruder challenge. For this procedure, an adult C57BL/6J mouse ("resident") was individually housed for 24 hrs prior to the test. An adolescent *Grin1* knockdown or wild type mouse ("intruder") was introduced to a sex-matched resident and behavior was video-recorded. After 15 min of social interaction, the resident mouse was placed under a wire cup, and the pair remained together for 2 hours, when the intruder was anesthetized and perfused. Non-social challenge controls were introduced to an empty cage and an empty wire cup. Results indicate that, in contrast to the marked deficits in Fos induction observed in adulthood, adolescent *Grin1* knockdown mice have significantly increased levels of Fos in cingulate cortex, infralimbic cortex, and lateral septum, following either a social challenge or exposure to a novel environment. These results suggest that the hypersociability phenotype in adolescent *Grin1* knockdown mice is associated with developmental increases in neuronal activation. Findings will be compared to profiles of Fos expression in young adult *Grin1* and wild type mice (postnatal day 60-65), to investigate the window for emergence of the deficient neuronal activation observed in older *Grin1* knockdown mice, relevant to age-dependent social phenotypes.

Title: Maternal diabetes as a risk factor for psychiatric disorders in the offspring: A new animal model of schizophrenia?

Authors: *A. CHANDNA, C. A. THAI, Q. GREBA, N. KUHLMANN, C. A. BRYCE, V. A. CAMPANUCCI, J. G. HOWLAND
Physiol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Inflammatory responses to infection during pregnancy increase the risk of neurodevelopmental psychiatric disorders such as schizophrenia in the offspring. However, whether maternal diabetes leads to a similar inflammatory state with long-term consequences for the offspring is not known. A major source of inflammatory signaling observed in diabetes is activation of the receptor for advanced glycation end products (RAGE). Interestingly, several studies have shown increased RAGE activation in psychiatric disorders. Thus, our hypothesis is that maternal diabetes creates a proinflammatory state, triggered largely by RAGE signaling, that alters normal neural development of the offspring. We tested this hypothesis in rats using the streptozotocin (STZ; 50 mg/kg; i.p.) model of maternal diabetes during the last week of pregnancy. Following STZ treatment, we observed a significant increase in protein expression of RAGE and the pro-inflammatory nuclear factor NF-κB in the forebrain of the offspring (postnatal day 0). Electrophysiological characterization of hippocampal cultures grown from the offspring of STZ-treated dams also showed a striking increase in excitability. Using whole-cell current clamp techniques, neurons from the offspring of diabetic rats showed a robust increase in the number of action potentials generated in response to a series of 500 ms depolarizing current steps. Further analysis of the action potentials generated also showed that hippocampal neurons from the offspring of diabetic rats generated action potentials of larger amplitudes and faster rise

and decay times. When tested in a battery of cognitive tasks in early adulthood, the offspring of STZ-treated dams had significantly lower prepulse inhibition than control offspring (22.9% vs. 42.7%) without changes in anxiety or recognition memory. In an operant-based task, STZ offspring did not differ from controls on a visual discrimination task but took significantly longer to shift to a new strategy to solve the task (i.e., set-shift; controls: 52.3 trials, STZ: 75.9 trials). These results suggest that maternal diabetes alters normal hippocampal development of the offspring, effects that may be mediated by RAGE signaling. Given the types of cognition affected in early adulthood, this preparation may be useful as a rodent model for some aspects of schizophrenia.

Title: Neurodevelopmental role for VGLUT2 in pyramidal neuron plasticity and spatial learning

Authors: H. HE[1], A. H. MAHNKE[2], S. DOYLE[1], N. FAN[1], C.-C. WANG[2], B. J. HALL[2], Y.-P. TANG[1], F. M. INGLIS[2], C. CHEN[1], *J. D. ERICKSON[1]
[1]Neurosci., LSUHSC, NEW ORLEANS, LA; [2]Dept. of Cell and Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: The level and integrity of glutamate transmission during postnatal development plays an important role in the regulation of pyramidal neuron structure and plasticity, and in cognition. The synaptic release of glutamate is mediated predominantly by VGLUT1 and VGLUT2 in cortico-limbic circuits. An important developmental window for the maturation of VGLUT1-encoded transmission in pyramidal neurons occurs during the 2nd and 3rd postnatal weeks in rodents. We hypothesize that VGLUT2 may play an important role in this process as it is

expressed in a considerable number of VGLUT1-containing developing synapses throughout the forebrain, and then either disappears, is inducible, or is retained in subsets of excitatory neurons into adulthood. To assess a potential neurodevelopmental role for VGLUT2 in pyramidal neuron plasticity, and in cognition, we have generated recombinant VGLUT2 knockout mice and inactivated VGLUT2 in cortico-limbic circuits throughout development. We used a Morris water maze to evaluate spatial learning and memory. Novelty-induced exploratory activity was measured in an open-field chamber. Hippocampal CA1 field potentials were evoked by constant current stimuli to CA3 Schaffer collateral commissural projections while recording field potentials in the *stratum radiatum* of CA1. We measured LTD, LTP, paired-pulse facilitation and input-output function. Region-specific changes in VGLUT1 and VGLUT2 expression was performed by Western and immunohistochemical analysis. We show that VGLUT2-deficiency in Emx1-$Cre^{+/+}$VGLUT2$^{fx/fx}$ mice results in reduced evoked glutamate transmission, release probability, and LTD at CA3-CA1 synapses during a formative development period (P11-14). In adults, CA1 dendritic arbor and spine number are reduced together with LTP and the levels of synaptic markers spinophilin and VGLUT1. VGLUT2-deficient mice exhibit increased novelty-induced exploratory activity, yet impaired spatial learning and memory; endophenotypes similar to NMDA receptor knockdown mice. Remarkably, the impairment in spatial learning can be partially restored by selectively increasing NMDA-receptor mediated glutamatergic transmission in adult mice *in vivo*. Our results support the notion that LTD induced by LFS in young CA3-CA1 connections may involve plasticity in VGLUT2-encoded vesicle release. Furthermore, our data suggest that VGLUT2 transmission in cortico-limbic circuits during development is critical for the maturation of normal structure and plasticity of CA1 pyramidal neurons and that such glutamatergic deficiency leads to cognitive malfunction as observed in NMDA receptor implicated psychiatric disorders.

Title: Outcomes of intrauterine asphyxia in the full term rat

Authors: *J. J. MORGAN[1], C. D. TULBERT[2], J. OLSON[3], G. A. KLEVEN[4], A. E. RONCA[2]
[1]Obstetrics & Gynecology, Wake Forest Univ., WINSTON SALEM, NC; [2]Obstetrics & Gynecology, [3]Ctr. for Biomolecular Imaging, Wake Forest Sch. of Med., Winston-Salem, NC; [4]Psychology, Wright State Univ., Dayton, OH

Abstract: Intrauterine asphyxia, observed in 1-6 out of every 1,000 live full term births and nearly 60% of preterm births, is a component of many obstetric complications, including infection, preeclampsia, maternal diabetes, and intrauterine growth restriction. Numerous population-based studies show risk for developing schizophrenia is more than doubled following intrauterine asphyxia. The mechanistic link between intrauterine asphyxia and schizophrenia has yet to be elucidated. Intrauterine asphyxia causes an acute lack of oxygen in the blood, resulting in metabolic acidosis, hypercapnia, and hypoxia. Preclinical models have identified postnatal sequelae involving oxidative stress and inflammation, as well as alterations in the dopamine (DA) system that parallel abnormalities found in the schizophrenic brain. In particular, preclinical studies have identified an increased sensitivity to DA agonists, consistent with observed increases in DA activity in prodromal schizophrenic populations, suggesting a key DA system disturbance observed in the brain at the onset of schizophrenia can be induced by asphyxia at birth. How DA supersensitivity arises from birth asphyxia is unknown, but it is developmentally regulated, meaning that DA sensitivity may be preventable with early identification and intervention. However, there is no way to identify an individual that will develop DA supersensitivity prior to symptom onset.
The aim of this experiment was to identify changes in the neurochemistry of forebrain dopamine targets using *in vivo* magnetic resonance spectroscopy at ages prior to the emergence of DA supersensitivity. We observed developmental changes in the dorsal striatum (Str) and medial prefrontal cortex. In Str, the ratio of glutamine (Gln) to glutamate (Glu) measure on postnatal day (P) 7 was significantly increased in birth asphyxiated rats (APX) compared to non-asphyxiated (NON) littermates ($p=.030$), normalizing thereafter. On P35, APX show reduced Glu+Gln in the Str ($p=.018$) and increased Glu in the mPFC, relative to NON ($p=.028$). Str GABA was increased in APX at P7 ($p=.023$) and then decreased at P60 ($p=.007$) relative to NON. Further experiments are identifying *in vitro* dopamine metabolite and receptor levels in scanned brains.

Title: The effects of "housing-stress" manipulations and sex differences on the wheel-induced feeding suppression in adult rats

Authors: *A. MASTROIANNI, R. EIKELBOOM
Psychology, Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: Excessive exercise has been implicated in the etiology of Anorexia Nervosa (AN) as they are highly co-morbid (Davis, 1997). The wheel-induced feeding suppression (WIFS) rodent model suggests a paradoxical relationship between exercise and feeding, which may parallel with aspects of AN. The WIFS model has found that adult male rats introduced to a running wheel will reduce feeding for 8-12 days compared to non-wheel controls. Wheel rats experience a drop in body weight, which is maintained as long as there is wheel access (Afonso & Eikelboom, 2003). The WIFS occurs despite increasing energy expenditure through high levels of running. In addition to exercise, stress has been shown to reduce feeding (Vallès et al., 2000). The stress levels of rats may be mitigated through pair or group housing, as avoiding isolation better mimics their natural colonies (Sharp et al., 2002). A pilot study has found that the WIFS was 33% shorter in pair housed females and 50% shorter in pair housed males, compared to earlier studies using individually housed male rats. This suggested that pair housing may have offered protection against the WIFS. METHODS: Since AN is more prevalent in females, female adult rats were housed individually (n=32) or in pairs (n=32; 16 pairs). Within each condition, half of the rats were given access for a running wheel for 32 days, while the remaining animals were housed in cages with locked wheels. Wheel revolutions, body weight and food intake were measured daily. It was predicted that individual housing, presumably more stressful, would result in a larger and longer lasting WIFS compared to pair housed wheel rats. RESULTS: Pair housed rats showed fewer wheel turns than individual rats; anecdotally, the female pair rats ran in the wheel together, potentially a gender-specific trait. Paired and individually housed wheel rats dropped in weight compared to non-wheel controls. A brief, yet pronounced, WIFS occurred in all (paired and individually housed) female wheel rats; much shorter in duration than typically seen in males. The feeding results suggest that pair housing failed to significantly alleviate the WIFS in female wheel animals. A male replication will allow for exploration of gender differences in WIFS and housing-stress conditions.

Title: Social play behavior in rats prenatally treated with valproic acid

Authors: *P. SAFT[1,2], B. BRUG[1,2], M. PÉREZ-POUCHOULÉN[1,2], C. MORGADO-VALLE[1,3], L. I. GARCÍA[1,3], M. E. HERNÁNDEZ[1,3], R. TOLEDO-CÁRDENAS[1,3], J. MANZO[1,3]
[1]Ctr. De Investigaciones Cerebrales Univ. Veracruzana, Xalapa, Mexico; [2]Doctorado en Neuroetología, Xalapa, Mexico; [3]Facultad de Medicina Univ. Veracruzana, Xalapa, Mexico

Abstract: Valproic acid (VPA) is an anticonvulsant drug used mainly to treat epilepsy and bipolar disorder. Previous studies demonstrated the teratogenic effect of VPA shown in some cases as an increased risk of autism spectrum disorder (ASD) in children of pregnant women who received VPA. This situation is used as a model for autism studies in rats. The model reproduces the main features of ASD such as anomalies in communication and altered social interaction. Play behavior is an important precursor of social behaviors in humans and other mammals. The study of play behavior allows determining whether there is any change in their performance and development. Thus, we measured play behavior in Wistar rats. We used several age groups: P22, P24, P26, P28, and P30. Both, a Sham (n = 8) and a treatment group (n = 8) were organized. For the treatment group a single intraperitoneal injection of 600mg/kg was applied to the pregnant female on E12.The behavioral test was performed every other day for 5 sessions.
To analyze play behavior we isolated pups for 24 hours before the test in a single box. Then we placed a pair of rats in an acrylic box of 20x40x60cm. The parameters analyzed were: latency to first contact, pinning frequency, frequency of sniffing, tail bit rate, frequency of complete defensive rotation and partial defensive rotation. One way repeated measure ANOVA was used for statistical analysis. There were no statistical differences between treatment and control groups in the parameters of: tail bit rate, pinning frequency, frequency of sniffing, frequency of

partial defensive rotation and complete defensive rotation. However there is an increase in the latency to first contact in the treatment group that may indicate less intention of social contact in comparison with the control group.

Title: Maternal ethanol consumption transiently increases Cajal-Retzius cells during corticogenesis

Authors: *A. G. SKORPUT, H. H. YEH
Physiol. and Neurobio., Dartmouth Col., Lebanon, NH

Abstract: Cajal-Retzius (CR) cells are among the earliest generated neurons in the embryonic cerebral cortex. They synthesize and secrete a number of factors that regulate radial and tangential migration of immature cortical neurons. Cajal-Retzius cells are depolarized by GABA, which has also been shown to influence neuronal migration. Abnormal migration of cortical neurons leads to cortical malformations and cognitive deficits, including Fetal Alcohol Spectrum Disorder (FASD). Here we hypothesize that ethanol exerts its effects on cortical migration in part by altering CR cell disposition. We report that, in the neonatal offspring, moderate maternal ethanol consumption increases the number of CR cells and diminishes their responsiveness to GABA.
Time pregnant Ebf2-GFP dams (GENSAT) were fed a liquid diet with or without 2% ethanol beginning on E9.5-E10.5, corresponding to the start of CR cell birth. The maternal blood-alcohol level (BAL) averaged 24$\pm$ 6 mg/dL, and this was comparable to the BAL in the embryos through birth (P0). Beyond P0, BAL became undetectable in the offspring, despite continued maternal ethanol consumption. GFP^+ CR cells in the marginal zone of the prefrontal cortex (PFC) and somatosensory cortex (SSC) were counted in 30μm fixed-frozen coronal sections. In both cortical regions, ethanol-exposed neonates (P0, P2) exhibited ~33% more CR cells relative to controls. This increase in CR cell number was transient, insofar as it was no longer apparent by

P4. Interestingly, at P6, counts of CR cells revealed a decrease in the PFC, but not in the SSC, of the ethanol-exposed group compared to controls, suggesting a cortical region-selective effect. Patch clamp analysis of CR cells revealed a reduced apparent potency of GABA in ethanol-exposed vs. control pups at P3 that was absent at P8.
Our results to date indicated that gestational exposure to ethanol increases the number of CR cells and alters their pharmacological properties in the neonatal cortex. These alterations in CR cell fate/function may be an important early contributor to the neurodevelopmental abnormalities in FASD. Ongoing studies are extending our initial observations to examine aspects of migration and circuit formation associated with CR cells in the developing cortex.

Title: Possible contribution of astrocyte dysfunction to myelination failure in Glutaric Acidemia Type I

Authors: *E. E. ISASI[1], L. BARBEITO[2], S. OLIVERA-BRAVO[1]
[1]Inst. Clemente Estable, Montevideo, Uruguay; [2]Inst. Pasteur de Montevideo, Montevideo, Uruguay

Abstract: Glutaric Acidemia Type I (GA-I) is a devastating neurometabolic disease caused by accumulation of high concentrations of glutaric acid (GA) derivatives in tissue and body fluids. White matter abnormalities together with striatal and cortical lesions are common pathologic findings in GA-I. The pathomechanisms involved are mostly unknown, including those leading to myelin disturbances. Our group has previously showed that, instead of neurons, astrocytes are the main cellular target of GA in a rat model of GA-I. We hypothesized that astrocyte dysfunction triggered by GA could participate in the white matter injury reported in GA-I. We first analyzed the effect of GA on cultured preoligodendrocytes (preOL) and differentiated oligodendrocytes (OL) obtained from postnatal day 1 rat cortices. 5 mM of GA, a concentration that enhanced astrocytes proliferation and oxidative stress in vitro, did not affect preOL survival,

functional status or proliferation. At that concentration, GA neither affect OL number or maturation, suggesting that OL lineage cells are not directly vulnerable to GA. However, conditioned media from astrocytes previously treated with GA, affected OL survival together with significant inhibition of process growth in surviving cells, 24h after treatment. Further, we studied OL lineage population and myelin status at 1, 12, 21 and 45 days after a single intracerebroventricular injection of GA in neonatal rats. The dose of GA employed mimicked GA-I encephalopathic crisis and survival rates. At 1 day post injection (DPI), animals that received GA did not present signs of striatal OL death, but a delayed decrease of striatal myelinated areas at 12, 21 and 45 DPI. In addition, OLs from GA-treated pups showed delayed cytotoxic signs such as swelling of ER and Golgi apparatus, decreased levels of myelin associated proteins and anomalous axonal myelin wrapping that persisted days after GA administration. Thus, our data allow to discard a cytotoxic direct effect of GA on preOL/OL cells, even at concentrations found during encephalopathic crisis. Instead, it suggests that astrocytes activated by GA may participate in GA-I myelination failure.

Title: Experience and the developing prefrontal cortex

Authors: *B. E. KOLB[1,1], R. MYCHASIUK[1], A. MUHAMMAD[1], Y. LI[1], D. O. FROST[2], W. COMEAU[3], R. GIBB[1]
[1]Canadian Ctr. Behav Neurosci, Univ. Lethbridge, Lethbridge, AB, Canada; [2]Pharmacol. and Exptl. Therapeut., Univ. of Maryland, Baltimore, MD; [3]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The prefrontal cortex receives input from all other cortical regions and functions to plan and direct motor, cognitive, affective, and social behavior across time. It has a prolonged development, which allows the acquisition of complex cognitive abilities through experience, but makes it susceptible to factors that can lead to abnormal functioning often manifested in neuropsychiatric disorders. When the developing prefrontal cortex is exposed to different environmental events the prefrontal cortex is set on different trajectories that predispose the entire cerebrum to changes later in life. Here we review and contrast the effects of pre-conceptual, prenatal, infant, juvenile and adult experiences on development of dendritic morphology (dendritic length and spine density) in the medial and orbital prefrontal regions (mPFC, OFC). Experiences include tactile stimulation, complex housing, various classes of psychoactive drugs, parental-infant interactions, stress, and play. All of these factors alter prefrontal pyramidal cell morphology, regardless of age at experience, although the changes are age and experience-dependent, and in some cases sexually-dimorphic. Some examples will illustrate. Prenatal stress (E12-16) increases spine density in mPFC and OFC when measured at weaning but decreases spine density when measured in adulthood. Olanzapine (an atypical antipsychotic) decreases spine density in mPFC and OFC when administered to infants but increases spine density when administered to juveniles. When play is manipulated in juveniles, the spine density is reduced in both mPFC and OFC in animals with extensive play relative to no play whereas dendritic length is decreased in mPFC and increased in OFC.
Not only do these early experiences alter neuronal morphology directly but they also change the way later experiences influence prefrontal morphology. For example, pre- or postnatal tactile stimulation as well as pre- and postnatal complex housing dramatically attenuate the effects of exposure to amphetamine in adulthood. Conversely, juvenile exposure to methylphenidate or adult exposure to amphetamine block the later effects of complex housing.
In sum, the prefrontal cortex can be changed dramatically by events beginning prenatally and continuing throughout the life span. These changes have effects on metaplasticity later in life. The plasticity and prolonged development of the prefrontal cortex provides an opportunity for continuing modification of the level of cognitive function but creates a potential susceptibility to the formation of abnormal circuitry leading to compromised behavioral functions.

Title: Long term effects of intermittent versus continuous methylphenidate administration in adolescent wistar kyoto rats

Authors: G. MILLER, ***E. C. PECK**, C. COSME, J. D. RICE, T. KOELTZOW
Bradley Univ., Peoria, IL

Abstract: Attention-deficit/Hyperactivity Disorder (ADHD) is the most commonly diagnosed childhood disorder. Methylphenidate (MPH) remains the most common pharmacological treatment for ADHD. Epidemiological studies indicate a relationship between ADHD and drug abuse. The current studies assessed the impact of chronic adolescent delivery of either high (3.2) or low (1.6) doses of MPH delivered either via intermittent, twice daily injections or continuously via osmotic minipumps. Wistar-Kyoto (WKY) represent a control strain for spontaneously hypertensive rats, the most commonly used rat model of ADHD, and have been suggested to model certain features of depression and anxiety. WKY were characterized by severe hypoactivity, severely decreased acquisition of the T-maze task, and robust behavioral anxiety. Intermittent MPH increased locomotor activity, but had no effect on T-maze performance or behavioral anxiety.
By contrast, continuous MPH treatment appears to enhance acquisition of the T-maze task and powerfully reduced behavioral anxiety. Continuing studies aim to relate these behavioral changes to alterations in dopamine transporter expression in prefrontal cortex and nucleus accumbens.

Title: Adenosine uptake by equilibrative nucleoside transporters is decreased in astrocytes from mice fetus exposed to gestational diabetes

Authors: *P. A. ARROYO ZÚÑIGA[1], C. SALOMON[1], E. GUZMAN-GUTIERREZ[1], F. WESTERMEIER[1], M. RICCA[3], P. CONGET[3], A. LEIVA[1], F. PARDO[1], L. SOBREVIA[2]
[2]Ginecologia y Obstetricia, [1]Pontificia Univ. Catolica De Chile, Santiago, Chile; [3]Univ. de Desarrollo, Santiago, Chile

Abstract: Gestational diabetes (GD) is a syndrome associated with high risk of developing cognitive alterations in the fetus. Physiological extracellular level of the endogenous nucleoside adenosine is determinant in maintaining cognitive functions and brain vascular reactivity. Adenosine transport via equilibrative nucleoside transporters (ENTs) in astrocytes is one of the mechanisms maintaining physiological extracellular levels of this nucleoside in the brain. However, adenosine plasma levels are increased in human fetus from GD, a phenomenon associated with low ENT1 isoform expression and transport activity. We here assayed whether adenosine transport and mouse ENT1 (mENT1) and mENT2 expression were altered by GD in astrocytes from fetal brains. **Methods**. Pregnant mice with normal (*Lepr*+/+) or reduced (*Lepr*^{db}/+) expression of leptin receptor were subjected to a glucose tolerance test (GTT). Animals were then separated into non-GD (*Lepr*+/+, 11 ± 0.1 µM/min area under the GTT curve) or GD (*Lepr*^{db}/+, 18 ± 0.15 µM/min area under the GTT curve) study groups. Fetal astrocytes were cultured under standard conditions (DMEM, 10% fetal bovine serum, 5% CO_2) and used for adenosine transport (0-500 µM adenosine, 2 µCi/ml [^{3}H]adenosine, 20 sec, 37ºC). mENT1 and mENT2 protein abundance was assayed in total protein extracts (80 µg) by Western blots. **Results**. Total adenosine uptake (mENT1+mENT2) was reduced (40%) in GD compared with non-GD cells. GD reduced the V_{max} (0.09 ± 0.04 and 0.04 ± 0.006 pmol/µg protein/sec, mENT1 and mENT2, respectively) without altering the apparent K_m (24 ± 11 and 67 ± 15 µM for mENT1 and mENT2, respectively) compared with non-GD cells (V_{max} 2.01 ± 0.04 and 1.1 ± 0.02 pmol/µg protein/sec, K_m 30 ± 11 and 60 ± 15 µM for mENT1 and mENT2, respectively). The mENT1 and mENT2 protein abundance was lower (61 and 35%, respectively) in GD compared with non-GD groups. **Conclusion.** GD associates with reduced mENT1 and mENT2-mediated adenosine transport likely due to reduced mENT1 and mENT2 protein abundance.

Title: Alterations in social behavior and mTOR signaling in the valproic acid-induced model of autism spectrum disorder

Authors: *Y. AHN[1], M. NAROUS[1], R. TOBIAS[1], B. HU[2], J. M. RHO[1]
[1]Pediatrics, Alberta Children's Hosp. Res. Inst., Calgary, AB, Canada; [2]Clin. Neurosci., Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada

Abstract: Valproic acid (VPA) has traditionally been used as an anticonvulsant in the treatment of epilepsy and migraine. Recent epidemiological evidence, however, suggests that maternal administration of VPA during pregnancy increases the likelihood of autism spectrum disorder (ASD) in the offspring. ASD is a highly prevalent, pervasive developmental disorder characterized by abnormal social interactions, communication deficits and ritualistic, repetitive behaviors. While the underlying basis of ASD remains obscure, speculation has increased around the mammalian target of rapamycin (mTOR) signaling pathway. Mutations affecting mTOR signaling result in disorders such as tuberous sclerosis complex (TSC). Since autistic behaviors are seen in many TSC patients, it follows then that disruptions in the mTOR pathway might underlie the pathophysiology of certain forms of ASD. Here, we demonstrate that prenatal exposure to VPA results in altered social behaviors described in ASD patients. To generate a model of ASD, 500mg/kg VPA (dissolved in saline; 250ug/mL) was injected IP in pregnant Wistar rats on E12.5 [PMID: 15238991]; controls received only saline. Dams were weaned on postnatal day (P)21 and the litters were sacrificed at P35. Non-play (allogrooming and sniffing) and play (complete, partial, and horizontal rotation) behaviors were quantified as measures of social interaction in rats prenatally exposed to VPA or saline. In the VPA-treatment group (n=9), rats showed significantly decreased non-play and play behaviors compared to their saline-injected counterparts (n=12) during 10-minute observation periods (24% and 100% decrease, respectively; $P<0.05$ one-way ANOVA). During this period, VPA-induced ASD rats also spent less time allogrooming (80% decrease; $P<0.05$ one-way ANOVA). To examine whether the behavioral changes noted by reflect alterations in mTOR signaling, we measured biomarkers using Western blots prepared from lateral temporal neocortices, specifically upstream pAkt and downstream pS6 and p4EBP1. In VPA-induced ASD (n=3), pAkt, pS6, and p4EBP1 levels were significantly decreased compared to saline-injected controls (n=4; 35.7%, 33.4% and 52.8% decreases, respectively; $P<0.05$ one-way ANOVA). Our data, contrary to expectations based on the existing literature, indicate that prenatal VPA exposure triggers a down-regulation of mTOR signaling. While these findings may be specific to the prenatal VPA model of ASD, our results

provide additional evidence that alterations in mTOR signaling may play a role in the pathogenesis of ASD.

Title: Ultrasonic communication in rats: Post-weaning but not post-adolescence social isolation leads to social impairments - Phenotypic rescue by re-socialization

Authors: *D. SEFFER, H. RIPPBERGER, R. K. W. SCHWARTING, M. WÖHR
Psychology, Philipps-University of Marburg, Marburg, Germany

Abstract: Rats are social animals in which rough-and-tumble play during adolescence has an important role for social development. Separation from conspecifics during this phase is known to impair social behavior. Post-weaning social isolation in rats is a widely used animal model to induce behavioral phenotypes and changes in neural development relevant to psychiatric disorders like schizophrenia (Fone & Porkess, 2008).
Ultrasonic vocalizations (USVs) are an important component of the rat's social behavioral repertoire. Rats emit distinct types of USVs, which serve as situation-dependent affective signals with important communicative functions. Low-frequency 22-kHz USVs occur in aversive situations such as fear-conditioning and lead to freezing behavior in the recipient, indicating an alarming function. In contrast, high-frequency 50-kHz USVs are produced in appetitive situations such as rough-and-tumble play and induce social approach behavior, supporting the notion that they serve as social contact calls (Wöhr & Schwarting, 2007).
Here, we tested whether social isolation impairs social approach behavior in response to playback of pro-social 50-kHz USVs and whether isolation-induced deficits depend on the time period of isolation during development. Male rats were housed in one of the following conditions: group housing, short-term isolation, i.e. 24 hours, or long-term isolation, i.e. 28 days. Rats were isolated either as weanlings with three weeks of age or as post-adolescent young adults with seven weeks of age, after going through rough-and-tumble play. As recent findings demonstrate that social deficits can be improved by peer intervention (Yang et al., 2011), we also

tested for phenotypic rescue in this paradigm by exposing a subgroup of rats to one additional week of peer-rearing. Subsequently, all rats were tested for social approach behavior in response to 50-kHz USVs. As acoustic control stimuli served 22-kHz USVs and background noise. While group-housed and short-term isolated rats displayed approach behavior in response to pro-social 50-kHz USVs, post-weaning long-term social isolation lead to a pronounced deficit, since rats displayed avoidance rather than approach behavior when exposed to 50-kHz USVs. Such deficits were not observed after post-adolescence long-term social isolation, indicating a critical period for social development during puberty. Importantly, approach deficits to 50-kHz USVs induced by post-weaning long-term isolation were reversed by peer-mediated re-socialization. This phenotypic rescue highlights the importance of social experience for affiliative behavior.

Title: Effects of early life stress on ionic currents in the CNS neurons and neuro-behaviors and its attenuation by natural sounds

Authors: *T. SHIRASAKI, R. HAMASAKI, F. SOEDA, K. TAKAHAMA
Dept. Env. Mol. Hlth. Sci., Grad. Sch. Pharm. Sci., Kumamoto Univ., Kumamoto, Japan

Abstract: Early life stress (ELS) has been implicated in psychiatric diseases, such as depression and schizophrenia, in adulthood. In this study, we investigated the influence of ELS on neurotransmitter responsiveness of single brain neurons and on various neuro-behaviors in Wistar rats. ELS was applied by maternal deprivation (MD) and white noise (WN). [Methods] Neonatal Wister rats were isolated from their mother and siblings, or exposed to WN at 85 dB for 4 hours a day during postnatal day (PND) 2 to 9. During WN exposure, pops were separated from their mother but reared with siblings. GIRK2 mRNA level in the hippocampus of pops was measured at PND10 and ionic currents in acutely dissociated neurons were measured during PND10 to 15 using perforated whole-cell patch-clamp technique. Behavioral tests were done at 1 month after birth. All experiments were conducted in strict accordance with the Guidelines of the Japanese Pharmacological Society and Kumamoto University for the Care and Use of Laboratory

Animals. [Results] MD augmented 5-HT-incused G-protein coupled inwardly rectifying K^+ (GIRK) channel currents in ventral hippocampal CA1pyramidal neurons (1.1±0.1 → 3.6±0.6 pA/pF) and decreased both dopamine-induced GIRK channel currents (2.1 ±0.6 → 0.9±0.4 pA/pF) and glutamate-induced cationic currents (16.3 ± 2.2 → 10.4 ± 1.3 pA/pF) in dopaminergic ventral tegmental area neurons. GIRK2 mRNA level in the hippocampus was reduced but that in ventral CA1 area was not affected by MD stress. Behaviors in the open-field, plus-maze and hole-board tests were not affected by MD stress. Interestingly, when pops were exposed to the music of little birds and the sound of a stream together with MD stress, the augmentation of 5-HT-induced GIRK channel currents was relieved (1.5±0.4 pA/pF). WN also augmented 5-HT-induced currents in ventral CA1 pyramidal neurons (2.0±0.4 pA/pF) but the influence was weaker than that of MD stress. In the same group of neurons, GABA-induced Cl^- currents were decreased from 54.8±10.8 to 36.2± 3.7 pA/pF and the ratio of neurons responding to baclofen was largely increased from 44% to 76% by WN stress. Noradrenaline-induced GIRK channel currents in locus ceruleus neurons were not affected by WN stress. The numbers of head dips and crossing from the wall-side area to the center area and the time spent in the center area in 5 min were increased from 8.1± 2.4 to 10.9±4.2 times, 3.7±2.6 to 6.5±1.6 times, and 2.8±1.6 to 6.4±3.6 %, respectively in hole-board test. These suggest that 1) ELS may alter the responsiveness of developing brain neurons to neurotransmitter, 2) effects of ELS may depend on the kind of stress and 3) soothing natural sound may attenuate the effect of ELS.

Title: The effects of P7 HI injury on visual attention in a rodent model, and therapeutic benefits of caffeine treatment

Authors: *M. L. ALEXANDER[1], A. SMITH[1], T. ROSENKRANTZ[2], R. H. FITCH[1]
[1]Psychology, Univ. Connecticut, Storrs Manfld, CT; [2]Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: Hypoxic Ischemic (HI) brain injury is common among children born prematurely (< 35 weeks) or at very low birth weight (VLBW; < 1500 grams). In these populations,

injuries can follow reperfusion failure, intracranial bleeding, increased ventricular pressure, or drops in blood pressure/flow. HI injuries can also occur in term-born infants with birth complications where blood and/or oxygen are reduced. Long-term cognitive/behavioral impairments following HI injury are evident in both in preterm and term-injured populations, and include cerebral palsy, epilepsy, and cognitive delays (e.g., deficits in attention, language, and/or learning). Children diagnosed with PVL (a non-hemorrhagic HI injury) also show impairments on visual memory, recognition, and spatial tasks. Finally, children born prematurely show deficits in visual attention (as measured behaviorally and by evoked potential) related to alterations in dorsal stream activity. With regard to protective treatments, caffeine is a non-selective adenosine antagonist that has been used to promote respiratory drive in premature infants. Previous studies have demonstrated neuroprotective effects of caffeine in these babies, and also in rodent models of early HI. The current study employed a postnatal day (P)7 HI rodent model to assess the therapeutic potential of caffeine treatment in reducing subsequent impairments on a visual attention task. Wistar rats received HI surgery on P7 (right common carotid artery cauterized with 2 hrs 8% oxygen) while shams received a skin incision and open air for 2 hrs. HI and sham animals were injected with either 10 mg/kg of caffeine or saline after surgery. In adulthood, animals underwent visual attention (5-choice serial reaction time; CCRT) testing for a period of two months. Data show that P7 HI injured rodents exhibit significant deficits in visual attention, and also reveal a therapeutic benefit of caffeine treatment in HI injured animals as measured by attention indices.

Title: Improved longitudinal learning performance following treatment with inter-alpha inhibitor proteins in neonatal hypoxic-ischemic rats

Authors: *S. W. THRELKELD[1], E. DUGAS[1], C. A. HILL[3,4], C. GAUDET[2], L. MABARDI[2], Y.-P. LIM[5], B. S. STONESTREET[3,6]

Hosp., Providence, RI; [5]Pathology, [6]Pediatrics, [4]Alpert Med. Sch. of Brown Univ., Providence, RI

Abstract: Neonatal hypoxia-ischemia (HI), commonly associated with preterm birth and very-low birth weight, is accompanied by a prolonged neuro-inflammatory response. This response has been linked to injury progression and severity, which may mediate long-term neurobehavioral outcome. Inter-alpha-Inhibitor proteins (IAIPs) have been shown to significantly reduce inflammation in a model of neonatal sepsis and brain infarct size in an adult rodent stroke model. The current study sought to investigate the effects of IAIPs on long-term neurobehavioral outcome in a rat model of neonatal hypoxia-ischemia. At birth, animals were randomly assigned into one of three groups (Sham n= 12, HI n=13, HI+IAIPs n=9). On postnatal day (P) seven, 30mg/kg IAIPs or saline was administered prior to hypoxia and again 24 hours after HI. Spatial and non-spatial learning was assessed during juvenile (P38-49) and adult periods (P84-95) using the Morris water maze (MWM) and a non-spatial water maze. Juvenile results, for the MWM task revealed a significant effect of injury, with HI and HI+IAIP subjects performing worse than shams. However, results for the juvenile non-spatial task showed that HI animals took longer to locate the hidden platform as compared to sham and HI+IAIP subjects. In adulthood, HI+IAIP treated subjects no longer showed a deficit relative to shams on the spatial water maze task, while HI subjects continued to show impairments as compared to shams. Finally, while no deficit was seen in the HI+IAIP group as compared to shams on the adult non-spatial task, HI animals showed persistent learning impairments. The current results reveal that treatment with IAIPs after neonatal HI improves multimodal learning performance across juvenile and adult maturational periods. These data suggest that IAIP may serve as a novel anti-informatory treatment to reduce neonatal brain injury and improve long-term behavioral outcome.

Title: Effects of neonatal hypoxic ischemic brain injury on rapid auditory processing and spatial working memory

Authors: *A. L. SMITH, M. L. ALEXANDER, J. J. CHROBAK, R. H. FITCH
Dept. of Psychology, Univ. of Connecticut, Storrs, CT

Abstract: Conditions of reduced oxygen and/or blood flow in the developing brain (hypoxia/ischemia or HI) are associated with tissue damage, as well as cognitive and/or motor deficits of varying degree. In the premature infant, HI may occur through intra-cranial bleeding or deficiencies in circulatory regulation, while in the term infant HI often results from prolonged labor, placental dysfunction, or other birth events. Damage to the hippocampus, cortex, corpus callosum as well as enlargement of the ventricles are frequently seen, although patterns of damage vary depending on the timing of initial injury. These injuries can be modeled in rats, with damage experimentally induced in the postnatal day 7 pup (P7) thought to roughly equate to that seen following term HI in infants. Research has shown that male rats with HI on P7 display deficits in rapid auditory processing, as well as spatial learning.
The current study sought to replicate previous findings that male rats with an induced HI injury show deficits on a rapid auditory processing (RAP) task. Based on previous data, we hypothesized that male P7 HI rats would be significantly impaired when compared to shams. Following auditory testing (gap detection), a subset of subjects (Group A) were tested on a delayed match-to-position radial water maze paradigm. This task allowed a more detailed characterization of the memory impairments associated with postnatal HI injury. Group B subjects received additional (more complex) auditory testing. Using two different behavioral tasks on the same group of animals, this further allowed us to assess whether impairments in RAP were associated with, or independent from, impairments in spatial working memory. Findings replicated RAP deficits in HI males, with HI subjects significantly impaired on gap detection (indicating deficits in the ability to detect rapidly changing cues). Subjects in Group B also evidenced HI deficits on more complex acoustic tasks. Within Group A, HI males performed significantly worse than sham animals in regards to working memory errors made. However, early RAP performance was not predictive of working memory deficits. These results suggest that HI effects are evident on “independent” neural systems, and degree/patterns of damage may differ within subjects.

Title: Adenosine 2A receptors contribute to striatal injury after neonatal hypoxia-ischemia

Authors: *R. C. KOEHLER[1], B. WANG[1], L. J. MARTIN[2], Z.-J. YANG[1]
[1]Dept Anesthesiol Critical Care Med., [2]Dept Pathology and Neurosci., Johns Hopkins Univ., BALTIMORE, MD

Abstract: Striatal medium spiny neurons are highly vulnerable to hypoxia-ischemia (H-I) in term newborns. Approximately half of these striatal neurons express adenosine 2A (A2A) receptors. Because A2A receptors are coupled to adenylate cyclase and PKA activation, we tested the hypothesis that an A2A receptor antagonist would attenuate phosphorylation selectively at PKA-sensitive sites on dopamine- and cAMP-regulated phosphoprotein-32 (DARPP32), NMDA receptor NR1, and Na,K-ATPase and provide protection of neurons in putamen after H-I. Anesthetized newborn piglets were subjected to 40 min of ventilation with 10% O_2 and 7 min of airway occlusion. At 5 min after reoxygenation, piglets received vehicle or 1 of 3 doses of the A2A receptor antagonist SCH58261 (0.01, 0.1, or 1 mg/kg, iv) followed by a continuous infusion for 6 h (0.0033, 0.033, or 0.33 mg/kg/h, iv, respectively). At 4 days of recovery, the density of viable neurons in putamen in the H-I group treated with vehicle was 19±9% (±SD; n=7) of the sham value (n=8). Neuronal density was significantly increased to 33±8%, 43±11%, and 40±9% in the SCH58261 groups treated with the low (n=7), medium (n=8), and high doses (n=7), respectively. Treatment with medium dose of SCH58261 attenuated the H-I-induced phosphorylation of the PKA-sensitive sites Thr34 DARPP-32, Ser897 NR1, and Ser943 Na,K-ATPase, but had no effect on phosphorylation of the PKC-sensitive sites Ser896 NR1 or Ser23 Na,K-ATPase at 3 h of recovery. The drug also blunted H-I-induced increases in the oxidative stress markers, nitrotyrosine and carbonyls. Because A2A receptors can also contribute to cerebral vasodilation, cortical perfusion was monitored with laser-Doppler flowmentry. However, post-treatment with SCH58261 did not alter the recovery of laser-Doppler flow, which returned to baseline levels within 1 h. We conclude that A2A receptors contribute to loss of a subpopulation of neurons in putamen after reoxygenation from H-I. The mechanism of toxicity may be related to DARPP-32-dependent phosphorylation of PKA-sensitive sites on NR1 and on Na,K-ATPase, thereby augmenting excitotoxic-induced oxidative stress after reoxygenation.

Title: A critical role of vascular endothelial growth factor (VEGF) in germinal matrix-intraventricular hemorrhage

Authors: *C.-Y. KUAN, D. YANG, J. BAUMANN, Y.-Y. SUN, H.-C. LIANG, S. POTTER
Devl Bio, Cincinnati Children's Hosp, CINCINNATI, OH

Abstract: Germinal matrix-intraventricular hemorrhage (GMH-IVH), the most important neuorological complication of preterm birth, affects approximately 12,000 infants each year in the USA and causes either neonatal death or permanent diabilities depending on the severity of hemorrhage. While past research has elucidated GMH-IVH as a result of both vascular fragility and disturbance of cererbal blood flow, the signaling mechanism of tenuous vascular integrity in permature brains is unclear. Here we test the hypothesis that hyper-stimulation of vascular endothelial growth factor (VEGF) signaling in the unique envionment of germinal matrix may activate neuovascular proteases and trigger IVH.

To test this hypothesis, we used a tetracycline-regulated transgenic system to express murine VEGF in the telencephalic germinal matrix by crossing either GFAP-tTA (Tet-Off) or Nestin-rtTA (Tet-On) drivers to the Tet-respondent TetO-VEGF-A164 mice. This transgenic strategy led to over-growth of endothelium incompletely covered by pericytes, similar to the immature vascular rete detected in human fetal brains. Gene-profiling and biochemical analysis indicated that early effector of VEGF include transcriptional factors ETS1 and HIF2α, the VEGF/PDGFβ/TGFβ signaling pathways, MMP-9, and cathepsin. By E18, bitransgenic embryos developed ventricular dilation and IVH from avascular periventricular areas resulted from Caspase-3 activation and regression of blood vessels. In contrast, antenatal treatment with steroid (betamethasone) significantly decreased the incidence of hemorhage, similar to its effects in human perterm infants.

Together, these results not only introduce a transgenic mouse model that recapitulates the full spectrum of disease presentation from GMH to IVH to ventriculomegaly, but also suggests a pathogenic cascade from VEGF to neurovascular proteases that interacts with important risk factors, such as perinatal hypoxia (via HIF2a) and infection (through MMP activation). This new experimental model offers opprotunities to develop biomarkers and therapeutic strategies in perinatal GMH-IVH.

Title: FTY720 mitigates infection-sensitized hypoxic-ischemic brain injury in newborns by blocking T-cell recruitment

Authors: *Y.-Y. SUN[1], D. YANG[1], J. BAUMANN[1], D. LINDQUIST[2], I. LEWKOWICH[3], C.-Y. KUAN[1]
[1]Div. of Developmental Biol., [2]Div. of Radiology, [3]Div. of Cell. and Mol. Immunol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Intrauterine infection (chorioamnionitis) and the ensuing fetal inflammation response sensitizes brain vulnerability to secondary hypoxic-ischemic (HI) insults in newborns. While a critical role of microglia in infection-sensitized neonatal HI brain injury is well established, the functions of blood-borne immune cells, especially T lymphocytes and Th17 cells, are yet to be determined. It is important to understand the roles of T-cells in neonatal HI brain injury for at least two reasons. First, preterm infants with elevation of CD45RO+ active T-cells in the cord blood tend to develop white-matter injury (Lancet 358: 1699, 2001). Second, FTY720, a FDA-approved drug for treating multiple sclerosis, inhibits the sphingosine 1-phosphate (S1P) receptor signaling to block T-cell infiltration into the CNS. Because FTY720-treated subjects maintain adequate resistance to bacteria infection, this oral medication may attenuate neuroinflammation without increasing the risk of severe sepsis, if T-cells contribute to infection-sensitized HI injury in neonates significantly.
To test the roles of T cells in neonatal infection/HI, we first determined that IL-23 receptor (a Th17 cell marker) was elevated and S1PR1 was reduced in the blood mononuclear cells of both preterm infants with chorioamnionitis and 7-day-old rat pups at 4 hour following LPS/HI injury (0.3 mg/kg LPS, IP injected 4 h before the start of the Rice-Vannucci model of unilateral cerebral HI). This result suggests the possibility of infection/HI-induced S1P signaling activation and mobilization of Th17 cells. Next, we conducted comparative study between administering

FTY720 (1.5 μg/g, IP) or saline at 1h after LPS/HI for mechanistic and efficacy investigation. These experiments showed that FTY720 markedly inhibited NF-kB signaling and microglia activation after LPS/HI injury and significantly reduced the resultant brain tissue loss and white-matter damage. Moreover, FTY720 blocks T-cell, including Th17 cell, infiltration into the brain with evidences ranging from immunostaining, quantitative RT-PCR analysis of Th17 cell markers, and fluorescence-activated cell sorting (FACS). Surprisingly, we found that FTY720 has no direct inhibitory on microglia in both in-vivo and in-vitro experiments.
Together, these results have two implications. First, the blood-borne T-cells, or Th17 cells alone, have a pivotal role in "priming" microglia in response to infection-sensitized neonatal HI. Second, using agents like FTY720 to block T-cell entry into the brain may be an effective strategy of brain protection against infection/HI injury of newborns.

Title: Gliotransmitter release from reactive hippocampal astrocytes results from enhanced Na+/H+ exchange following *in vitro* ischemia

Authors: *P. CENGIZ[1,2], P. KENDIGELEN[3], D. KINTNER[1], V. CHANANA[1], E. FIDAN[1], G. BEGUM[4], P. FERRAZZANO[1], D. SUN[4]

Abstract: Hypoxia ischemia is one of the common causes of brain injury in neonates. After HI, the intracellular pH (pHi) drops resulting in acidosis. Na+/H+ exchanger isoform 1 (NHE1) is abundantly present in the rodent hippocampus and is one of the primary proteins involved in maintenance of pHi under physiological and pathological conditions. We recently reported that inhibition of NHE1 resulted in less hippocampal pyramidal neurodegeneration and improved long-term learning and memory in the mouse model of neonatal HI. NHE1 expression in hippocampal reactive astrocytes was significantly up-regulated after HI. We hypothesize that the intracellular acidosis after HI in hippocampal reactive astrocytes results in sustained activation of

NHE1 and leads to subsequent neuronal damage. In the current study, using an in-vitro ischemia model (oxygen/glucose deprivation and reoxygenation, OGD/REOX), we investigated whether inhibition of NHE1 reduces intracellular Na+/H+ dysregulation and the gliotransmitter release from reactive hippocampal astrocytes. Hippocampal astrocytes cultured from postnatal day 4 mouse brains underwent 2 h exposure to OGD and 1-24 h REOX. The pH-sensitive dye BCECF and Sodium Green were used to determine changes of pHi and intracellular Na+. Glutamate and cytokine release into the media were determined using the amplex® red glutamic acid/glutamate oxidase assay kit and ELISA, respectively. Statistical analysis was performed using either T-test or Mann-Whitney Rank Sum test and ANOVA with Bonferroni post-test, for two and multiple comparisons respectively. 2 h OGD led to a significant increase in NHE1 expression and 1.6-fold elevation in NHE1 activity, which was sustained for 1-5 h REOX. Inhibition of NHE1 activity with its potent inhibitor HOE642 reduced sustained H+ efflux and Na+ overload in astrocytes after OGD/REOX. Blocking NHE1 activity also decreased the release of gliotransmitters (glutamate and the pro-inflammatory cytokines such as IL-1, IL-6 and TNFα) from hippocampal astrocytes at 1-5 h REOX. Administration of either HOE642 or the excitatory amino acid transporter inhibitor TBOA attenuated glutamate release. These data suggest that over-stimulation of NHE1 activity disrupt both H+ and Na+ homeostasis in hippocampal astrocytes following in-vitro ischemia, which not only reduces Na+-dependent glutamate uptake but also increases cytokine release. Title: Porcine model for designing cell-based regenerative strategies in postnatal brain injury

Authors: *N. ISHIBASHI[1], L. KOROTCOVA[1], K. AGEMATSU[1], R. A. JONAS[1], V. GALLO[2]
[1]Children's Natl. Heart Inst., [2]Ctr. for Neurosci. Res., Childrens Natl. Med. Ctr., WASHINGTON, DC

Abstract: The subventricular zone (SVZ) maintains the largest source of neural stem/progenitor cells in the postnatal and adult brain. Defining the regenerative potential of SVZ neural stem/progenitor cells is crucially important to design cell-based regenerative strategies in postnatal brain injury. However, recent evidence demonstrates that the cellular and anatomical features of the human SVZ are dissimilar from the well-studied rodent SVZ. In spite of these crucial differences, both technical and ethical difficulties prevent the investigation of cellular/molecular and functional mechanisms in the human SVZ. Here we show that the juvenile porcine SVZ (1-15 weeks of age) shares the same anatomical and cellular structure of the human SVZ. The adult human lateral-SVZ (L-SVZ) comprises four distinct cellular layers. In particular, the hypo-cellular gap and astrocyte ribbon are unique features of the human L-SVZ. The juvenile porcine L-SVZ also comprised four layers, including the $GFAP^+$ astrocyte ribbon. In the second layer of the porcine L-SVZ, we observed the presence of Dcx^+ neuroblasts. It has been recently shown that the presence of neuroblasts in this layer is a specific feature of human neonates/infants. In human neonates/infants, the astrocyte ribbon is absent in the anterior L-SVZ. This was also observed in the porcine SVZ. Furthermore, porcine SVZ $GFAP^+$ processes expressed the immature neuroepithelial marker Vimentin, as demonstrated in human neonates. Another significant difference between human and rodent SVZ is the existence of a neurogenic niche in the outer SVZ (O-SVZ). We identified the O-SVZ in the posterior porcine SVZ, based on total cell density, the presence of $Ki67^+$ cells, and of $Sox2^+Pax6^+$ progenitor cells. Furthermore, it is well established that the O-SVZ contains outer radial glia (O-RG) cells. $Pax6^+Sox2^+Vimentin^+$ O-RG was also found in the porcine O-SVZ. In the O-SVZ, $Vimentin^+GFAP^+$ processes of O-RG cells not only extend radially, but also line the lateral ventricle. This mesh-like distribution of $GFAP^+$ fibers was reported only in the human fetus. This indicates that the porcine model allows us to investigate development of the O-SVZ, an important cell source in the evolution of the gyrencephalic neocortex. Altogether, our studies in the porcine SVZ will provide novel insights on cellular/molecular and developmental mechanisms of the human SVZ under both normal physiological and pathological conditions, and will help in designing novel cell-based regenerative strategies in postnatal brain injury.

Title: Chronic valproic acid and phenobarbital administration impacts neurogenesis after neonatal stroke.

Authors: S. GEORGE[1], S. RAJA[1], Y. TU[1], A. KWAN[1], D. BOOTHE[2], *A. M. COMI[1]
[1]Kennedy Krieger Inst., BALTIMORE, MD; [2]Auburn Univ., Auburn, AL

Abstract: Background: Stroke in the immature brain usually presents with seizures 12-24 hours after the insult which are treated with anticonvulsants. Post-stroke neurogenesis in the SGZ of the immature brain is decreased and may contribute to the long-term cognitive impairments seen. Histone deacetylase (HDAC) inhibitors prevent HDAC from blocking DNA transcription and replication. Valproic acid (VPA) is a HDAC inhibitor, but also enhances GABA neurotransmission and blocks sodium channels. Phenobarbital keeps chloride channels open longer, thereby enhancing GABA. In higher concentrations, phenobarbital can block sodium channels and block glutamate.
Objective: To determine the impact of chronic HDAC inhibition or phenobarbital on post-stroke neurogenesis in the immature brain.
Methods: P12 CD1 mice received right common carotid artery ligation and acute seizures were scored. Mice were assigned to receive either VPA (200mg/kg) or phenobarbital (25mg/kg) or vehicle twice daily from P16 to P28. 5-bromo-2'-deoxyuridine (BrdU; 50mg/kg) was injected five times between P24 and P26 prior to sacrifice on P42. Percent of brain atrophy was quantified and immunohistochemistry was performed for analysis of neurogenesis (Brdu/NeuN colabeling). In a subset of mice, serum was collected at P26 and analyzed for concentrations of VPA or phenobarbital.
Results: Among injured VPA-treated mice, there was a 208% increase in BrdU/NeuN-positive cells in the ipsilateral dentate gyrus (DG) when compared to counts in saline treated mice ($p= 0.024$); there was a 55.4% increase in contralateral DG ($p= 0.023$). In uninjured VPA-treated mice, there was a 49.4 and 61.5 % increase in cell counts in contralateral and ipsilateral DG versus vehicle treated ($p= 0.007$ and 0.004 respectively).
Our prior serum studies showed that half-lives for VPA and phenobarbital in neonatal mice after chronic dosing are much lower than previously reported. Peak drug levels of VPA in serum one

hour after dose were: 251.7 ± 13.3 mcg/ml with a maximum half-life of 1.24 ± 0.26 hours. The average peak phenobarbital level was 20.5 mcg/ml with an average half-life of 3.5 hours. Half-life of phenobarbital was significantly longer in injured vs. unligated mice (4.4 ± 0.4 and 3.2 ± 0.2 hours respectively, p= 0.025).
Conclusion: VPA causes increased neurogenesis; the neurogenesis in injured hippocampi was more marked. This is likely related to HDAC inhibition given that previous studies with Trichostatin A produced similar results. We are currently investigating chronic phenobarbital effects upon post-stroke neurogenesis. Chronic administration of valproate and phenobarbital results in very short half-lives.

Abstract: Hypothermia has been proposed for reducing neuronal damages in the brain induced by hypoxia-ischemia (HI). However, little is known about the effect of hypothermia on immature brains of neonatal mice with HI. In this study, we conducted histological examination in the cortex during 4 first postnatal weeks and neurobehavioral tests.
To induce cerebral ischemia in postnatal 3 days ICR mice, we performed right common carotid artery ligation followed by hypoxia (6%O2, 37°C) for 30 minutes. Immediately after HI, mice were divided into a hypothermia group (32°C) or a normothermia group (37°C) by placed in a chamber in a water bass at the stable temperature for 24h. Mice were sacrificed at P4, P7 and 5 weeks. We focused on 1) the laminar structure in the cortex using Cux1/Ctip2 immunohistochemistry, 2) the change of the number of neurons, and 3) the comparison in

expression for myelin basic protein (MBP) between ischemic and contralateral normal hemisphere.
Histological analysis revealed that the laminar distribution was observed within 7 days after normothermia treatment. At 4 weeks of age, there appeared to be a district loss of volume with the structural changes in the deep layers. The thickness of layers V/VI was 1.9×106 μm2 in the ischemic hemisphere, while that in the normal hemisphere was 1.2×106 μm2. In addition to the focal necrosis in the deep layers, there was significant decrease in the intensity of immuoreactivity for MBP by 27% in the ischemic hemisphere. The density of neurons was not different between both hemispheres (Ipsi, 1070cells/μm2; Contra 1076cells/μm2). Hypothermia immediately after HI improved these developmental disturbances to form the normal laminar structures. Hypothermia also could improve neurological outcomes in the beam balance test and rotarod test at 4 weeks of age.
Because 3-d-old in rodents coincides with gestation between 23-32 weeks of gestational age in very preterm infant human in which infants have a risk for cerebral palsy (CP), these results reveal pathophysiology of CP and may contribute to hypothermal therapies of CP patients.

Title: Phosphorylation of NR2B Tyr1472 contributes to brain injury following neonatal hypoxia-ischemia in mice

Authors: *R. KNOX[1], D. YANG[1], A. BACH[1], S. LOWENSTEIN[1], M. LAM[1], T. NAKAZAWA[2], T. YAMAMOTO[2], D. FERRIERO[1], X. JIANG[1]

Abstract: Neonatal brain hypoxia-ischemia (HI) is an important contributor to morbidity and mortality in infants and children. However, there are few treatments. We have recently demonstrated that Src Family Kinase (SFK) activity and NMDA receptor (NMDAR) tyrosine phosphorylation are increased following neonatal HI in mice. Particularly, phosphorylation of the NR2B subunit at Tyr1472 is upregulated rapidly after HI (peaking at 15min after HI). However, it is unknown whether NR2B tyrosine phosphorylation contributes to HI brain injury.

To determine the functional significance of tyrosine phosphorylation of NR2B, we obtained mice with a knock-in mutation of the Tyr1472 site to phenylalanine (Y1472F). Neonatal HI was performed on postnatal day 7 wildtype (WT) or Y1472F mice and brain injury was examined at postnatal day 12 with cresyl violet and Perl's iron stain. Y1472F mice have decreased brain injury compared to WT mice (median=16.25, n=18 in WT mice and median=11, n=23 in Y1472F mice, p=0.034) with the largest decrease in brain injury in the cortex (p=0.013). There were no gender differences in brain injury. This study provides the first evidence that phosphorylation of the NR2B subunit at Tyr1472 contributes to HI brain injury. Our study suggests that therapies aimed at reducing NMDAR tyrosine phosphorylation could reduce injury in the human neonates with hypoxic-ischemic encephalopathy. Future studies will elucidate the molecular mechanisms by which Y1472 mediates cell death in the developing brain.

Title: Structural and functional cortical development following early cerebral hypoxia ischemia

Authors: *G. OR, S. RANASINGHE, A. IEVINS, P. S. MCQUILLEN
Pediatrics & Neurol., UCSF, San Francisco, CA

Abstract: Neonatal cerebral hypoxia-ischemia (HI) disrupts both anatomic and functional cortical plasticity. Although impaired plasticity is accompanied by loss of parvalbumin expression, no evidence is found for loss of functional inhibition. Instead, early HI reduces the mature cortical response to an optimal visual stimulus suggesting disrupted development of excitatory circuits. Many aspects of structural and functional neuronal development are dependent upon neuronal activity. To understand abnormal cortical development following neonatal HI, we are correlating early EEG activity with glutamate receptor expression, dendritic structure and synapse formation following HI at postnatal day 2 (P2).
EEG is recorded from biparietal, epidural electrodes in awake, unrestrained rats from P3 - P21

and processed to measure amplitude-integrated EEG (aEEG), interburst interval (IBI) and to identify specific activity patterns as measures of brain maturation. Expression of synaptosomal glutamate receptor subunits and post-synaptic density proteins is quantified. Cortical pyramidal neuron morphology is visualized using a double adenoviral transduction to produce sparse, brightly labeled fluorescent neurons in all cortical layers. Selected cortical neurons are analyzed for dendritic length, volume and Sholl analysis using Imaris FilamentTracer. Synapse formation is quantified from synapsin immunofluorescence.
In control animals, background activity increases with development. In moderately injured animals following hypoxia ischemia at P2, the aEEG upper voltage margin was significantly lower from P3 to P11. Depressed activity in injured animals result from both decreased spectral power in all frequency bands ($P<0.01$) and a significantly prolonged population distribution of IBI's. Notably, by P14 the background activity in HI animals recovered to values comparable to the control group.
Consistent with these activity changes, there was decreased expression ($P<0.05$) of all the glutamate receptor subunits, PSD95 and CaM kinase at P3, following HI. Expression of glutamate receptors recovered to normal by P7, preceding the recovery of EEG background.
Layer V pyramidal neuron dendrites manifest markedly simplified branching with parvalbumin immunohistochemistry. Analysis of pyramidal neuron morphology and synapse counts is underway.
These observations suggest that neonatal HI impairs maturation of both excitatory and inhibitory circuits with delayed morphologic and functional neuronal development. Understanding early network development following neonatal brain injury will identify specific interventions to optimize recovery.

Title: Expression and function of Toll-like receptor 4 in hypoxic cerebellar microglia

Authors: L. YAO[1,2], J. LU[1,3], A. HAO[2], E.-A. LING[1], *C. KAUR[1]
[1]Dept Anat, Natl. Univ. Singapore, Singapore, Singapore; [2]Dept. of Histology and Embryology, Shandong Univ., Jinan, China; [3]Def. Med. Envrn. Res. Inst., DSO Natl. Labs., Singapore, Singapore

Abstract: Hypoxic injury damages cells including Purkinje neurons in the neonatal cerebellum. It was surmised that inflammatory mediators derived from microglia might contribute to this process. Toll-like receptors (TLRs) have been reported to induce microglial activation and production of proinflammatory cytokines in brain and spinal cord injuries. However, their role in the developing neural tissues following a hypoxic injury has remained uncertain. We report here TLR4 expression and its putative roles in hypoxic developing cerebellar microglia both *in vivo and in vitro*. Damage to Purkinje neurons and their dendrites was observed following exposure of 1-day old Wistar rats to hypoxia (5% oxygen +95% nitrogen) for 2h. TLR4 expression was detected in cerebellar microglial cells at different time points following hypoxic exposure. TLR4 immunofluorescence expression in microglia was markedly enhanced 3 days after hypoxia. Western blot analysis also showed a significant increase in TLR4 expression in the cerebellum after the hypoxic exposure. *In vitro*, by RT-PCR, western blot and immunofluorescence staining, TLR4 mRNA and protein expression levels were most drastically increased in primary cultures of microglia and BV-2 cells subjected to hypoxia. To further dissect the function of TLR4 in microglial activation and the associated molecular mechanism, we depleted TLR4 by small interfering RNA (siRNA) transfection and antibody neutralization. Knockdown of TLR4 effectively reduced hypoxia-induced upregulated expression of tumour necrosis factor-alpha (TNF-α), interleukin-1β (IL-1β) and inducible nitric oxide synthase (iNOS) in BV-2 cells. TLR4 knockdown-mediated inhibition of inflammatory cytokines was coupled by inhibition of NF-κB activation. Neutralization of TLR4 with its antibody also attenuated the hypoxia-induced expression of TNFα, IL1β and iNOS in primary cultured cerebellar microglia. We conclude that TLR4 expression in cerebellar microglia may be linked to regulation of inflammatory mediators via an NF-κB signaling pathway; hence, interference withTLR4 in activated microglia may reduce cerebellar damage caused by hypoxia. Title: Hippocampal theta bursts drive oscillatory entrainment of the neonatal prefrontal cortex under physiological conditions but not after hypoxic-ischemic injury

Authors: *M. D. BROCKMANN[1], M. KUKOVIC[1], M. SCHÖNFELD[2], J. SEDLACIK[2], I. L. HANGANU-OPATZ[1]

Abstract: The coactivation of prefrontal and hippocampal networks in oscillatory rhythms is critical for precise information flow in mnemonic and executive tasks. We recently showed that even during early development the two brain regions are tightly coupled and their communication is directed via synaptic projections. Discontinuous theta-band activity in the neonatal hippocampus (HP) drives the entrainment of local prefrontal networks in oscillatory bursts with distinct spatial and temporal organization. It is very likely that this precise directed communication underlies the correct maturation of prefrontal-hippocampal networks and its disease-related impairment correlates with cognitive deficits at adulthood. To test this hypothesis, we assessed the effects of an early hypoxic-ischemic (H-I) injury on the functional prefrontal-hippocampal development. We focused on a mild/moderate peri-neonatal injury, which has been previously identified as cause of poorer cognitive performance in children at school age in the absence of massive morphological changes and gross behavioural deficits. The magnitude of injury in a rodent model of H-I [ligation of the common carotid artery followed by exposure to 5% oxygen at postnatal day (P)2], was assessed by T2 weighted MRI and post-mortem histology (Nissl and GFAP immunostaining).
To decide on the functional consequences of H-I, we performed extracellular multielectrode recordings in vivo in the prefrontal cortex (PFC) and CA1 area of the intermediate HP from neonatal (P6-8) rats with either severe or mild/moderate injury and compared them with sham-operated pups. Pups with mild/moderate H-I injury showed reduced discontinuous oscillatory activity of the neonatal PFC and prominent disruption of gamma-band entrainment of local networks. Additionally, the functional communication between the PFC and HP is impaired as shown by synchronization and causality analysis. The coherence between prefrontal and hippocampal oscillations was significantly lower in rats with mild/moderate H-I injury when compared with sham-operated animals. Moreover, the drive from HP to PFC was suppressed after mild/moderate H-I. These results indicate that even in the absence of major morphological insult, mild/moderate profoundly impairs the functional maturation of prefrontal-hippocampal networks and may account for cognitive deficits at adulthood.

Title: Altered FMRP/mTOR signaling and autism-like behavior in an animal model of EOP

Authors: *M. LECHPAMMER, P. M. KLEIN, M. R. WATTS, A. M. BACH, F. E. JENSEN
Neurobio., Childrens Hosp. Boston, Boston, MA

Abstract: Studies of postmortem brain from infants with severe encephalopathy of prematurity (EOP) following perinatal hypoxic / ischemic (HI) injury show altered markers of excitotoxic and oxidative stress in neurons and glia. Premature brain injury is associated with later life neurobehavioral deficits and autism. Here we investigated whether HI may alter the neuronal expression of components of the fragile X mental retardation protein (FMRP) and mammalian target of rapamycin (mTOR) signaling pathways, both implicated in genetic causes of autism. We have previously shown these pathways to be dysregulated in postmortem human brain after premature brain injury. We hypothesized that their dysregulation during critical periods of cortical development may contribute to later life cognitive impairment and autism-like deficits. We used a rat model of selective white matter injury / EOP in P6 Long-Evans rat pups, induced by unilateral carotid artery ligation followed by severe hypoxia (6% O2 for 1 h). Healthy controls were age and sex matched littermates without treatment. Western blot analyses for total and phospho-FMRP(Ser^{499}) and mTOR downstream targets p70S6K and phospho-p70S6K(Thr^{389}) were performed. In the rat model of EOP (n=6) a suppression of FMRP and phospho-FMRP was observed 24 hours after HI brain injury compared to controls (n=5). A significant concomitant overexpression ($p<0.05$ vs. control) of both p70S6K and phospho-p70S6K was recorded in the same animals, mirroring expression pattern of FMRP/mTOR molecular components previously observed by our group in the patients with EOP. In addition, we assessed behavior in the three-chambered sociability test in young adult male Long Evans rats (P31-33; n=14) that were previously exposed to a severe HI brain injury at P6. While the post HI rats had normal interactions in the unfamiliar/novel rat/object behavioral test, when a second novel rat was introduced to them in the subsequent phase of the assay, they continued to spend significantly more time with the first, now-familiar animal, as opposed to the shifted

preference of control rats ($p<0.0001$). Observed resistance to change represents an important autistic-like behavioral outcome in young adult animals exposed to HI brain injury in their infancy. Presented results suggest that HI brain injury may cause its long term sequelae via dysregulation of FMRP/mTOR cascade as otherwise observed in common syndromes of inherited mental retardation (e.g. Fragile-X syndrome and tuberous sclerosis) and also propose this signaling pathway as a possible new molecular target for the treatment of this as yet untreatable cause of later life neurobehavioral deficits.

Title: IRS-1 in dietary restriction neuroprotection against neonatal HI brain injury

Authors: *Y.-F. TU[1,2], C.-C. HUANG[3]
[1]Inst. of Clin. Medici, Tainan, Taiwan; [2]Emergency Med., Natl. Cheng Kung Univ. and Hosp., Tainan, Taiwan; [3]Departments of Pediatrics, Natl. Cheng Kung Univ. Hosp., Tainan, Taiwan

Abstract: Introduction: Perinatal hypoxic-ischemia (HI) is a major cause of neonatal mortality and of subsequent neurological disabilities among infants who survive it. Recently, dietary restriction (DR) is known to protect against neonatal HI brain injury. Since insulin signaling pathway is the main regulator of metabolism, we hypothesis that rats raised on dietary restriction protect against neonatal hypoxic-ischemia brain injury through activating insulin signaling pathway.
Materials and methods: Rats were grouped from postnatal day (P) 1: normally fed (NL) rats (litter size: 12) and DR rats (litter size: 18). On P7, rats were subjected to HI induced by modified Rice-Vannucci model and then their brain tissues are removed for molecular biological assay.
Results: DR rats attenuated apoptosis and reduced brain infarction volume after induction of HI brain injury on P7. The DR rats kept the expression of insulin receptor substance (IRS-1) even after HI injury. In contrary, IRS-1 in NL rats decreased soon after HI injury. In addition, IRS-1 in DR rats after HI activated PI3K/Akt which further protect against HI injury. This in vivo

finding was also tested in vitro. Over-expression of IRS-1 increased cell viability after oxygen-glucose deprivation (OGD) in hippocampus neuron cell lines (H19-7) and knockdown of IRS-1 reduced the cell viability after OGD. The correlated decrease of Akt level after knockdown of IRS-1 were also noted in H19-7.
Conclusions: Our findings indicated DR can protect against neonatal brain HI injury through activation IRS-1/ PI3K/Akt pathway.

Title: Investigation of mechanisms whereby uridine exhibits neuroprotective effects in a rat model of neonatal hypoxic-ischemic encephalopathy

Authors: *T. ALKAN[1], Z. MINBAY[2], M. CETINKAYA[3], B. GOREN[5], E. ORENLILI[4], M. CANSEV[4]
[1]Prof Dr Tülin Alkan Uludag Univ. Sch. Med., Bursa, Turkey; [2]Histology and Embrio., [3]Neonatology, [4]Pharmacol., Uludag Univ. Sch. of Med., Bursa, Turkey; [5]Physiol., Uludag Unin Sch. of Med., Bursa, Turkey

Abstract: Hypoxic-ischemic brain damage is a major cause of neurological morbidity and mortality in neonates and results with sequelae such as cerebral palsy, mental retardation, epilepsy and learning disabilities.
We previously observed that uridine reduces brain damage in a rat model of neonatal hypoxic-ischemic encephalopathy. In this study, we aimed to investigate the mechanisms whereby uridine exhibits neuroprotective effects in this model.
Hypoxic-ischemic encephalopathy was achieved by ligation of right common carotid artery followed by subjection to hypoxia (92% nitrogen and 8% oxygen) for 2.5 h in 7-day-old Sprague-Dawley neonatal rats which were then arranged in control or uridine group. Uridine or saline was injected intraperitoneally immediately after hypoxia and 24 and 48 hours after the first dose. Possible mechanisms of neuroprotection exhibited by uridine were investigated 72 h after the hypoxic-ischemic insult by evaluating the hemispheres for cross-sectional area, infarct volume, apoptotic markers and matrix metalloproteinase expression.

Uridine treatment significantly reduced the infarct volume, number of apoptotic cells and number of matrix metalloproteinase-expressing cells in the brain. The results suggest that neuroprotection provided by uridine involves its actions on apopitosis and matrix metalloproteinase expression in a rat model of neonatal hypoxic ischemic encephalopathy.

Title: Autophagy inhibition reduces neonatal mouse hypoxic-ischemic brain injury

Authors: *K. BLOMGREN[1,2], Y. SUN[2,4], H. LI[2,4], Q. LI[2,4], X. WANG[3], Y. UCHIYAMA[5], C. ZHU[2,4]
[1]Karolinska Institutet, Stockholm, Sweden; [2]Ctr. for Brain Repair and Rehabil., [3]Perinatal Ctr., Univ. of Gothenburg, Gothenburg, Sweden; [4]Dept. of Pediatrics, Zhengzhou Univ., Zhengzhou, China; [5]Dept. of Cell Biol. and Neurosci., Juntendo Univ., Tokyo, Japan

Abstract: Autophagy is a strictly regulated process involving bulk degradation of cytoplasmic macromolecules and organelles via the lysosomal system. Autophagy is induced under stress to maintain cellular homeostasis, but this may be either beneficial or detrimental depending on the cell type and conditions. Lack of autophagy-related gene 7 (*atg7*) renders cells incapable of autophagy induction. *Atg7*$^{flox/flox}$ mice were bred with mice expressing cre recombinase under a nestin promoter to disrupt *atg7* expression in brain neurons. Hypoxia-ischemia (HI) was induced in postnatal day 9 (P9) mice using the Vannucci model and injury was evaluated on P17. The tissue loss was 55.1 ± 4.5 mm^3 in *atg7* +/- mice [n=28] and 32.0 ± 5.0 mm^3 in *atg7* -/- mice [n=38], i.e. 41.9 % reduction in *atg7* -/- brains (p=0.001). The overall neuropathological scores were reduced in the *atg7*-deficient mice (11.9 ± 0.8 [n=38] vs. 6.4 ± 1.0 [n=28] mm3, p=0.0002) The DEVDase activity (caspase-3-like activity) was 35.4 ± 4.6 pmol/min.mg protein in *atg7* +/- mice [n=6] and 21.7 ± 3.9 pmol/min.mg protein in *atg7* -/- mice [n=10] (p=0.038). The number of cells immunopositive for active caspase-3 were significantly lower in the dentate gyrus

(214,000 ± 14,700/mm^3 vs. 144,000 ± 23,940/mm^3, p=0.022) , the cornu ammonis (CA1 to 3) (41,810 ± 3,243/mm^3 vs. 22,860 ± 4,685/mm^3, p=0.003) and the cortex (20,410 ± 1,918/mm^3 vs. 12,800 ± 2,991/mm^3, p=0.004) of *atg7* -/- mice compared with *atg7* +/- mice (n=11 /group). These findings indicate that targeting autophagy may be fruitful in ameliorating perinatal brain injury.

Title: Priming effects of hypoxic preconditioning on hypoxic/ischemic white matter injury through up-regulation AMPAR in the immature rats

Authors: *H.-K. PARK, L. JANTZIE, F. JENSEN
CLS 14060.3 Children's Hosp Boston, BOSTON, MA

Abstract: Hypoxia-ischemia(H/I) is a major factor in brain injury in premature infants and results in white matter injury, known as periventricular leukomalacia(PVL). Clinically, repeated H/I injuries are common. Experimental studies show a protective effect of recurrent H/I injury to neurons, termed “H/I preconditioning”. In cultured oligodendrocytes(OLs), sublethal oxygen glucose deprivation(OGD) results in an increase in expression of calcium-permeable GluR2 deficient AMPARs, with subsequently increased sensitization to later repetitive OGD(Deng et al. 2003). However, the effects of hypoxic preconditioning in vivo in white matter injury and specifically on OLs, is largely unknown. We examined the effect of hypoxic preconditioning prior to HI in a rodent model of PVL. Postnatal day(P) 5 Long-Evans rats were exposed to H/I(unilateral carotid ligation and hypoxia 1h 6% O_2) with or without hypoxic preconditioning at P3(1h 6% O_2), and were compared at P6 and P9 to control pups without hypoxia/ligation. White matter was evaluated at P6 or P9(n=10/group for each). Immunocytochemistry was performed for GluR4, and cell death (TUNEL staining) and double-labeled with cell specific markers for preOLs or mature OLs(O4, O1, MBP). Results indicate that H/I at P5 without prior hypoxia at

P3 did not induce significant injury, with no increase in TUNEL+cells or altered MBP at P6 or P9. However, rats that received hypoxia at P3 prior to P5 H/I demonstrated significant increases in TUNEL+cells in white matter at P6 compared to P5 H/I alone and sham controls. In these preconditioned pups, O1 cells and O1/O4 cell ratios were significantly decreased at P5(50±7, p=0.02) and P9(36±6, p=0.04), compared to P5 H/I alone(51±5 at P9) and controls(65±12 at P5, 55±8 at P9). In pups sacrificed at P5, 48 hours after exposure to hypoxia, OLs expressed increased GluR4 protein (219% of control, p<0.005). In-situ hybridization for GluR4 mRNA also showed increases in OLs in white matter (190% of control, p=0.03). Taken together, these results indicate that hypoxic preconditioning in the developing white matter may alter OL maturation and exacerbate OL susceptibility to secondary injury, in contrast to prior studies of neuronal protective preconditioning. Our results also suggest that hypoxia-induced increase in preOL GluR expression may all play a role in this increased susceptibility to white matter injury to recurrent H/I.

Title: Protective efficacy of the NKCC1 inhibitor bumetanide a rodent model of premature hypoxic-ischemic brain injury

Authors: *L. L. JANTZIE, M. Y. HU, H.-K. PARK, M. JACKSON, F. JENSEN
Neurol., Children's Hosp. Boston, Boston, MA

Abstract: Periventricular leukomalacia (PVL) is a major type of brain damage observed following hypoxia-ischemia (HI) in preterm infants and together with inflammation, is the most

common cause of cerebral palsy, neurodevelopmental delay, and epilepsy in this patient population. PVL is characterized by cerebral white matter injury and damage to immature oligodendrocytes (OLs), subplate, cortical neurons and deep gray matter structures. The Na+-K+-Cl- isoform 1 cotransporter (NKCC1) is highly expressed on neurons and astrocytes, and has been suggested to play a role in adult ischemia and neonatal seizures. As little is known about the expression of NKCC1 on OLs in the developing brain and whether NKCC1 expression is altered by HI in early life, we aimed to 1) investigate the developmental expression of NKCC1 in the immature rodent brain; 2) characterize the time course and cell-specific changes in NKCC1 expression following HI; and 3) investigate whether the NKCC1 inhibitor bumetanide protects against HI injury. We hypothesized NKCC1 is expressed on OLs during development and is upregulated following HI, and that bumetanide would attenuate HI-mediated injury in preterm equivalent rodents. NKCC1 expression was assessed in Long-Evans rats and PLP-EGFP transgenic mice from postnatal day 3 (P3)-P14 (n=6). A separate group of rats were subjected to unilateral carotid ligation and hypoxia at P6, and treated post-HI with 0.3mg/kg bumetanide q12 for 60h (n=7). Semiquantitative analyses reveal NKCC1 is expressed on OLs of all developmental stages and subplate neurons, throughout P3-P14, with a peak in expression from P5-P7. Following HI at P6, NKCC1 is significantly upregulated on cortical and white matter OLs at 6-24h ($p<0.05$). Similarly, NKCC1 is significantly upregulated on subplate neurons acutely following HI and on cortical neurons in and surrounding areas of HI injury at 6-72h ($p<0.05$). Post-HI administration of bumetanide significantly attenuates myelin basic protein injury scores (2.1 ± 0.4 vs. 1.0 ± 0.2, $p<0.05$) and reduces fluorojade cellular degeneration scores in the cortex (1.5 ± 0.3 vs. 0.6 ± 0.5) up to 7d post-HI. This is the first demonstration that NKCC1 is expressed on OLs during normal brain development and upregulated on OLs, cortical neurons and subplate neurons acutely following HI and that bumetanide protects against HI in the preterm equivalent rodent. These data suggest the relative overexpression of NKCC1 in the preterm window coincides with peak vulnerability to HI gray and white matter cell death. Further study is needed to understand the putative mechanisms of NKCC1-mediated injury in premature brain and the protective efficacy of bumetanide.

Title: The effect of neonatal hypoxia-ischemia on the retinal structure and function of rats

Authors: *S. JUNG[1,2], A. POLOSA[2], A. JOHNSTONE[1], M. GAUVIN[2], P. LACHAPELLE[2], P. WINTERMARK[1]
[1]Div. of Newborn Med., [2]Dept. of Ophthalmology and Neurology-Neurosurgery, Montreal Children's Hospital-Research Institute, McGill Univ., Montreal, QC, Canada

Abstract: **Background:** Birth asphyxia, i.e. insufficient delivery of oxygen and blood to the organs around the time of birth, leads to significant neurological complications including cerebral palsy, mental retardation and blindness. Although birth asphyxia has been extensively studied, relatively few studies explored the impact of neonatal HIE on the retinal tissue. Furthermore, eye examination is currently not part of the standard monitoring protocol of asphyxiated newborns.
Objective: The objective of the current study was to investigate the impact of neonatal hypoxia-ischemia (HI) on retinal function and cytoarchitecture.
Methods: Neonatal HI was induced in Long-Evans rat pups by left common carotid ligation followed by 2-hour hypoxia (8% oxygen) on postnatal day 10 (P10). At P60, electroretinograms (ERGs) were recorded in HI animals, as well as in control shams, in order to assess function of the retina. Animals were then sacrificed; their eyes were removed and fixed by immersion in 4% paraformaldehyde and subsequently embedded in resin. Sections of the retina were stained with toluidine blue, in order to investigate the cytoarchitecture of retinal cell layers.
Results: Compared to the control shams, ERGs of the HI animals demonstrated 30% reduction in the scotopic a-wave amplitude and 84% reduction in the scotopic and photopic b-wave amplitudes, suggesting that the function of the photoreceptors (where the a-wave is generated) was relatively preserved, whereas that of inner retinal neurons (where the b-wave is generated) was severely impaired. Supportive of the latter, retinal histology of the HI animals showed reduction in the thickness of the inner retina, including outer plexiform layer (none vs. 11.88±1.09 µm in controls), inner nuclear layer (17.44±4.29 µm vs. 26.66±3.40 µm), inner plexiform layer (18.46±26.10 µm vs. 50.69±0.16 µm) and ganglion cell layer (7.20±10.18 µm vs. 13.90±0.36 µm). In contrast, the photoreceptor outer nuclear layer remained intact in all HI animals (50.07±7.42 vs. 46.94±3.06 µm).
Conclusions: Our findings suggest that neonatal HI induces permanent damages to the structure and function of the inner retina (i.e. the layers of cells connecting the photoreceptors to the brain), but less so to the photoreceptors, which appear to be protected from HI insult. These findings may be explained by the fact that photoreceptors and inner retina have different blood

supplies (respectively choroid and retinal vasculature) and that these blood supplies may have different sensitivity to HI.

Title: Optical imaging spectroscopy of early haemodynamic changes in a rat model of neuroinflammation

Authors: *N. BRAY, F. BURROWS, S. ALLAN, I. SCHIESSL
Univ. of Manchester, Manchester, United Kingdom

Abstract: Inflammation is a major driver of cell death in the brain after ischaemic stroke, seizure activity and traumatic injury. In order to open avenues for medical intervention we need to acquire a better understanding of the very early stages of neuroinflammation and its impact on cerebral blood flow responses to neuronal activity.
In an established model of excitotoxicity, striatal injection of AMPA at a toxic dose causes cell death in the striatum after 24 hours. However, co-injection of AMPA with interleukin-1β (IL-1β, a pro-inflammatory cytokine) leads to cortical cell death in addition to striatal damage. When injected alone, IL-1β leads to little or no cell death. In this study we image the changes of the haemodynamic response in the rat barrel cortex after injection of AMPA, IL-1β, AMPA+IL-1β or vehicle with two-dimensional optical imaging spectroscopy. The somatosensory cortex of the anaesthetised animals was stimulated by mechanical whisker manipulation for up to 6 hours after injection. Markers of neuroinflammation (immunoglobulin G and neutrophils) were analysed using immunohistochemistry.
Animals injected with AMPA+IL-1β or IL-1β alone showed a decrease in the size of oxygenated blood response in the active whisker barrel over time. Injection of AMPA alone or vehicle caused little or no trend change in oxygenated blood response. An increase of immunoglobulin G was found in the ipsilateral hemisphere of the brains injected with IL-1β (with or without AMPA), indicating an increase in blood-brain barrier permeability.
This continuing research aims to further investigate the mechanisms behind IL-1β's effects on

the blood flow response. Since the reduction of blood flow response precedes neuronal death, it may be instrumental in deciding the fate of neurones at later time points.

Title: 2D imaging spectroscopy of the dynamic changes in blood perfusion during ischaemic stroke

Authors: *F. BURROWS, A. DENES, N. BRAY, S. ALLAN, I. SCHIESSL
Univ. Of Manchester, Manchester, United Kingdom

Abstract: The aim of this study was to quantify the dynamic changes in cortical blood perfusion in response to focal cerebral ischaemia in anesthetised mice with high temporal and spatial resolution.
Middle cerebral artery occlusion (MCAo) was induced by advancing a filament along the internal carotid artery to occlude the middle cerebral artery. Generally this model does not allow real-time monitoring of vascular and metabolic changes in the brain at the onset of ischaemia due to the surgical approach, which is time-demanding. Here, we are using a remote filament approach which allows recording changes before, during and after focal cerebral ischaemia in a controlled manner.
During the 2D imaging spectroscopy, data at four different illumination wavelengths is collected. This allows us to calculate micromolar changes in the concentration of oxy- and deoxyhaemoglobin.
Our results show the expected decrease in the concentration of oxyhaemoglobin in the occluded MCA and supplying cortical regions. After removal of the filament, the MCA vessel shows an increase in oxyhaemoglobin concentration in large areas of the cortex which are insufficiently reperfused even several hours after the stroke.
Our results suggest that 2D imaging spectroscopy with the remote filament approach enables

precise mapping of vascular and metabolic changes in the mouse MCAo model, which can contribute to a better understanding ischaemia-induced changes in the brain.

Title: Both central and haematopoietic-derived endogenous interleukin-1 contribute to brain injury after cerebral ischaemia in mice

Authors: A. DENES[1], F. L. WILKINSON[2], B. BIGGER[2], N. J. ROTHWELL[1], *S. M. ALLAN[3]

Abstract: Interleukin-1 (IL-1) is a key regulator of inflammatory responses in the periphery and in the brain. Interventions against IL-1 markedly protect against ischaemic brain injury in experimental stroke. Although IL-1 can be produced by both resident brain cells and immune cells, the relative contribution of central and peripheral sources of IL-1 to brain injury is not well understood.
Here we show that haematopoietic-derived IL-1 is a key driver of ischaemic brain injury, as wild type (WT) mice transplanted with IL-1αβ-deficient bone marrow after lethal irradiation displayed a significant (40%) reduction in infarct size induced by focal cerebral ischaemia compared to WT mice transplanted with WT bone marrow. This was paralleled by improved neurological outcome and the almost complete absence of splenic, but not liver-derived IL-1α, in WT mice lacking haematopoietic-derived IL-1. IL-1αβ KO mice transplanted with IL-1αβ-deficient bone marrow show a 60% reduction in infarct size and significantly reduced blood brain barrier injury compared to WT mice receiving WT bone marrow.
These results indicate that both central and haematopoietic-derived IL-1 are important

contributors to brain injury induced by cerebral ischaemia. Identification of the cellular sources of IL-1 could allow targeted interventions against IL-1-mediated inflammation in brain diseases.

Title: Systemic inflammation impairs cerebral blood flow after focal cerebral ischaemia

Authors: *K. MURRAY[1], W. M. HOLMES[4], K. DAVIES[2], S. WILLIAMS[2], A. PARRY-JONES[3], S. ALLAN[1]
[1]Fac. of Life Sci., [2]Fac. of Med. and Human Sci., [3]Manchester Academic Hlth. Sci. Centre, Salford Royal Hosp., Univ. of Manchester, Manchester, United Kingdom; [4]Glasgow Exptl. MRI centre, The Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Ischaemic stroke is characterised by an interruption in cerebral blood flow (CBF) and the extent of brain damage correlates with the time it takes to re-establish CBF. Neuroinflammation is a key dimension to cerebral ischaemia with evidence for an expansion of infarct core due to pre-existing infection or inflammation. Experimental work has shown that systemic inflammation exacerbates ischaemic damage via interleukin-1 (IL-1) and neutrophil dependent pathways. Preliminary data using magnetic resonance imaging (MRI) suggest that systemic IL-1 may influence CBF following reperfusion however the mechanisms through which systemic inflammation worsens stroke have yet to be elucidated. It was therefore the objective of the present study to investigate the effects of systemic IL-1 on CBF during early reperfusion in experimental stroke.
Transient focal cerebral ischaemia (60min) was induced in male wistar rats by intraluminal filament occlusion. Animals received intraperitoneal recombinant IL-1β (4μg/kg; n=8) or vehicle. Animals were transferred to a 7-Tesla magnet and remote filament reperfusion was performed. Repeated multi-slice diffusion weighted and perfusion weighted (arterial spin labelling) MRI was performed until 4h reperfusion. Perfusion maps were used to define hypoperfused tissue at risk of infarction and apparent diffusion coefficient (ADC) maps to define ischaemic damage. At 4h reperfusion animals were perfused, organs removed and brains fixed.

IL-1 caused a significant 2-fold increase in ischaemic volume at 3 and 4h reperfusion compared to vehicle-treated animals. IL-1 also led to a 3-fold increase in the volume and magnitude of tissue hypoperfusion on restoration of MCA patency at 15min, 1 and 2h reperfusion. This hypoperfused tissue progressed to infarction over 4h. Furthermore, immunohistochemistry highlighted a prominent role for platelet aggregates in clogging microvessels in IL-1 treated animals. These results reveal that IL-1 exacerbates ischaemic damage following stroke and suggests this injury is mediated by a platelet-dependent reduction in CBF due to microvessel obstruction.
Poor flow in the microcirculation due to systemic inflammation may lead to an accelerated collapse of salvageable tissue, thus reducing the time window and effectiveness of the only treatment available, thrombolysis. Ultimately, the goal of this research is to restore CBF after stroke by introducing treatment with IL-1 antagonists or platelet antibodies alongside thrombolysis.

Title: Inflammatory changes in peripheral organs and the cerebrovasculature of obese mice may mediate enhanced responses to experimental stroke

Authors: *M. HALEY, N. GORENKOVA, R.-A. PIPE, C. B. LAWRENCE
Fac. of Life Sci., Univ. of Manchester, Manchester, United Kingdom

Abstract: Obesity is a risk factor for stroke and is associated with conditions such as atherosclerosis and diabetes that predispose to cerebrovascular disease. Inflammation may play a key role in mediating this interaction, since obesity features a raised inflammatory profile that has previously been shown to be detrimental to stroke outcome. The aim of this study was to assess whether there are changes in the inflammatory states of the cerebrovasculature and white adipose tissue of obese mice that could mediate the effects of obesity on stroke outcome.
Focal cerebral ischaemia was induced by intraluminal filament occlusion of the middle cerebral artery in 16-to-20-week-old obese ob/ob and control (ob/-) mice. Ischaemic damage was

assessed at 4 and 24 hours post-stroke, as were the cerebrovascular, adipose and systemic inflammatory responses. Expression of tight junction proteins and inflammatory molecules were analysed in isolated brain microvessels. Structural changes to the cerebrovasculature resulting from ischaemia were assessed in situ using electron microscopy. The adipose tissue response to cerebral ischaemia was also evaluated by ELISA for inflammatory mediators and immunohistochemistry for immune cell infiltration, and was similarly assessed in C57BL/6J mice fed a high fat diet for 16 weeks.
The incidence of haemorrhagic transformation (HT), blood-brain barrier (BBB) breakdown and extent of ischaemic damage were increased in obese mice. Furthermore, HT and BBB breakdown were prominent at 4 hours in obese mice only. Adipose tissue inflammation was also worsened by stroke in obese mice. These data suggest that obese mice suffer worse damage to their cerebrovasculature that may accelerate the development of ischaemic damage, in which the adipose tissue response to stroke may play a role.

Title: The effect of tumor necrosis factor-stimulated gene 6 on brain inflammation in experimental ischaemic stroke

Authors: *H. F. BUGGEY, A. J. DAY, A. DENES, S. M. ALLAN
FLS, The Univ. of Manchester, Manchester, United Kingdom

Abstract: Ischaemic stroke carries a huge socio-economic burden, and systemic inflammation is a major contributor to stroke damage. Pro-inflammatory cytokine interleukin-1 (IL-1) is a key mediator of systemic inflammation, and is able to exacerbate the outcome of experimental stroke. This effect is known to be dependent on neutrophils. Tumor necrosis factor-stimulated gene 6 (TSG-6) is expressed under inflammatory conditions, and has a number of anti-inflammatory properties including inhibition of neutrophil migration. The therapeutic value of TSG-6 has been demonstrated in a number of inflammatory conditions, but it has never been investigated in stroke. To test whether TSG-6 can protect against IL-1-induced exacerbation of brain injury and inflammation after stroke, C57BL/6J mice (n=12) were injected

intraperitoneally with vehicle, IL-1 (20ng/kg), TSG-6 (5µg) or IL-1 + TSG-6 (20ng/kg + 5µg), followed by 20 minutes middle cerebral artery occlusion (MCAo) and 24h reperfusion. No significant effects of TSG-6 were observed neurological outcome. In contrast, a significant reduction was seen in the number of neutrophils in the ischaemic lesion of animals treated with IL-1 + TSG-6 compared to mice treated with IL-1 alone. Immunohistological staining with IgG showed that TSG-6 also showed some benefit in limiting IL-1-induced blood-brain barrier breakdown. Furthermore, animals administered IL-1 + TSG-6 also displayed a trend for reduction in the presence of haemorrhagic transformation when compared to IL-1 treated mice. The results suggest that TSG-6 inhibits neutrophil migration into the brain, which might have some benefits for outcome and preservation of the blood-brain barrier, although it is insufficient for full protection against IL-1-induced exacerbation of brain injury. Interactions between IL-1 and TSG-6 need further investigation.

Title: Up-down regulation of HO-1 and iNOS gene expressions by ethyl pyruvate via recruiting p300 to Nrf2 and depriving it from p65

Authors: *H. LEE[1], I.-D. KIM[1], J.-H. SHIN[1], S.-W. KIM[2]
[1]anatomy, Inha Univ., Incheon, Korea, Republic of; [2]Nano Sci. and Brain Dis. Res., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Ethyl pyruvate (EP), a simple ester of pyruvic acid, has been shown to exert robust neuroprotective effect in various neuropathological conditions, such as, cerebral ischemia and KA-induced seizure in animal models. The neuroprotective effect of EP is largely attributable to the anti-inflammatory effects of EP, which might be mediated by modulation of the NF-κB and p38 MAPK signaling pathways. In the present study, the authors reported a novel molecular mechanism underlying anti-inflammatory effects of EP. In normal BV2 cells, EP induced expression of hemeoxygenase 1 (HO-1) in a dose-dependent manner and nuclear factor E2-related factor 2 (Nrf2) was found to translocate from the cytosol to the nucleus beginning 30 min after EP-treatment, where it binds to the antioxidant response element (ARE) located on HO-1 promoter. EP dose-dependently suppressed nitrite production in LPS-treated BV2 cells, a

microglia cell line, wherein pre-treatment of EP was found to be more effective than co-treatment. As it has shown previously, I-kB degradation and p65 tanslocation to nucleus were conveyed normally in EP-treated cells, however, p65 binding to promoter was inhibited. We found that it is due to recruiting p300, a transcriptional co-activator of both Nrf2 and p65, to Nrf2 and depleting it from p65. EP-induced p300 squelching was confirmed by Nrf2 knockdown by Nrf2 siRNA. Together these results demonstrate that EP induced nuclear translocation of Nrf2, which binds to ARE along with p300, hampering iNOS expression via depleting p300 from p65. This is a novel anti-inflammatory mechanism conveyed by EP, which leads to enhanced protective effect by converging anti-inflammatory and anti-oxidative effects and might be applicable to various Nrf2-activating agents, such as phytochemicals.

Title: Astrocytic TGFbeta signaling limits the spread of immune responses and improves functional outcome after stroke

Authors: *E. CEKANAVICIUTE, N. FATHALI, J. HAN, K. P. DOYLE, M. S. BUCKWALTER
Stanford Univ., Stanford, CA

Abstract: TGFβ is a master regulatory cytokine that modulates the immune responses to ischemia or injury in a context-dependent fashion. All brain cell types express TGFβ receptors, but stroke caused by distal middle cerebral artery occlusion (dMCAO) leads to a marked increase in TGFβ upregulation and signaling in astrocytes and monocyte-lineage cells. The TGFβ

downstream effector phosphorylated Smad2 was observed in astrocytes in both ipsilateral and contralateral cortex after dMCAO. To alter TGFβ signaling after stroke in an astrocyte-specific manner, we constructed transgenic mice that express a mutant dominant negative TGFβ receptor in reactive astrocytes (DN mice). DN mice express a dramatic, astrocyte-specific upregulation of transgene expression by 12h after stroke that continues for at least 28 days. Three days after stroke, astrocyte activation in DN mice was more widespread than in controls, as indicated by 200% larger area occupied by GFAP+ cells on the opposite side of the stroke. Multiplex luminex assay and ELISA were used to measure the levels of 26 cytokines and chemokines 2 days after stroke. We detected a 2-10 fold decrease in brain TGFβ of DN mice in ipsilateral and contralateral cortex and in ipsilateral striatum, but no genotype-dependent changes in other cytokines and chemokines. Thus, astrocytic TGFβ signaling is required for an autocrine, positive feedback loop that specifically upregulates brain TGFβ after injury. TGFβ signaling-dependent changes in astrocyte phenotype coincided with increased monocyte activation: three days after stroke, DN mice showed 39% more CD68+ cell infiltration than controls in the stroke border, and over 120% more on the opposite side. These effects were accompanied by infarct expansion in DN mice: while the transgene did not alter the initial infarct size, by 7 days DN mice had 32% larger strokes than controls. To study how astrocytic TGFβ signaling affects stroke functional outcomes, we subjected DN mice and their wildtype littermates to a battery of behavioral tests for 4 weeks after photothrombotic stroke. DN mice performed significantly worse in the beam balance test and the modified Garcia test, which together cover multiple aspects of motor behavior. We conclude that reducing astrocytic TGFβ signaling inhibits stroke-mediated increase in TGFβ secretion and leads to abnormal spread of astrogliosis and inflammation. This increases the infarct size within the first week, and correlates with worse motor performance for at least 4 weeks. Thus, astrocytic TGFβ signaling induces brain TGFβ production and limits the spread of the immune response, resulting in improved functional outcome after stroke.

Title: NGAL (lipocalin 2) and microglial activation and function

Authors: *C. XING[1], E. H. LO[2]
[2]Dept. of Radiology and Neurol., [1]Massachusetts Gen. Hospital, Harvard Med. Sch., CHARLESTOWN, MA

Abstract: Neutrophil gelatinase-associated lipocalin (NGAL), also known as lipocalin-2, is a 25 kDa protein belonging to the lipocalin superfamily. NGAL captures and transports iron particles to the inner cell by interacting with specific membrane receptors (24p3R or megalin). Traditionally, NGAL is released by activated neutrophils as part of innate immunity. More recently, it has been proposed that NGAL may also participate in inflammation and remodeling after ischemia. Here, we asked whether NGAL can directly modify microglia function, long considered a critical part of CNS pathophysiology. Primary microglial cultures were derived from rat cortex. Morphological changes were observed with phase-contrast microscopy. Cellular function was assessed with phagocytotic and migration assays. Gene expression levels were measured with RT-PCR. Cytokine and growth factor levels were quantified with ELISA. After NGAL treatment for 24 hrs, normally ramified "resting" microglia converted into a long-rod morphology with reductions in peripheral branching. mRNA levels of NAPDH oxidase and TLR2 increased by 2-fold after NGAL treatment for 4 hrs. NGAL treatment significantly increased TNFα and IL-10 release, and reduced IGF-1 production by microglia. No significant changes in IL-1β and VEGF levels were detected. NGAL-treated microglia also showed enhanced phagocytotic capacity. But there were no detectable effects on microglia migration. This study suggests that NGAL may regulate microglial activation and function. How NGAL-mediated microglial responses contribute to the pathophysiology of various CNS disorders warrants further investigation.

Title: Post-ischemic treatment with BML-111, a lipoxin A_4 receptor agonist, reduces infarct size and neuroinflammation in a rat model of stroke

Authors: K. E. HAWKINS, H. S. CHO, J. FRANKOWSKI, *E. CANDELARIO-JALIL
Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Lipoxin A_4 (LXA_4) is an anti-inflammatory mediator derived enzymatically from arachidonic acid by the concerted action of lipooxygenases. Binding of LXA_4 to its receptor (FPR2/ALX) has pro-resolution effects on inflammation. Virtually nothing is known of the role of LXA_4 on neuroinflammation following cerebral ischemia. BML-111 is a FPR2/ALX receptor agonist and has been recognized to play a similar role as LXA_4 in anti-inflammatory responses. We hypothesized that treatment with BML-111 would reduce post-ischemic inflammation and provide neuroprotection in a rat model of ischemic stroke. Rats were subjected to 90 minutes of transient middle cerebral artery occlusion and sacrificed after 48 hours of reperfusion. Animals received BML-111 or the vehicle. The first dose (1 mg/kg) was given intravenously 10 minutes after the onset of reperfusion and another dose 24 hours after reperfusion. Pro-inflammatory markers such as myeloperoxidase (MPO), a neutrophil marker, and matrix metalloproteinases -2 and -9 (MMP-2 and MMP-9) were evaluated at 48 hours after reperfusion. Post-ischemic treatment with BML-111 significantly reduced infarct size and blood-brain barrier (BBB) damage as seen with 2,3,5-triphenyltetrazolium chloride (TTC) staining and brain IgG extravasation, respectively. BML-111-treated animals had significantly reduced neutrophil infiltration as seen by decreased MPO expression in the ipsilateral cerebral cortex compared to vehicle-treated animals as determined by western blotting. BML-111-treated animals also had significantly decreased levels of MMP-9 in the ipsilateral cortex and striatum compared to animals receiving the vehicle. However, levels of MMP-2 did not significantly decrease in the ipsilateral striatum and only approached significance in the ipsilateral cortex as seen with gelatin-substrate zymography. These data indicate that activation of the FPR2/ALX receptor with BML-111 results in the reduction of infarct size possibly through the attenuation of the inflammatory response following ischemic stroke.

Title: Toll-like receptor 2 provides protective effects on ischemic demyelination and oligodendrocyte death in a subcortical white matter stroke model.

Authors: *J. CHOI[1,2], J.-H. KIM[1], Y. KANG[1], B. KIM[1]
[1]Brain Dis. Res. Ctr., Inst. For Med. Sciences, Ajou Univ. Sch. of Med., Woncheon-Dong, Yongtong-Gu, Suwon, Korea, Republic of; [2]Dept. of Neurol., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Ischemic lesion involving subcortical white matter constitutes more than 20% of all ischemic stroke subtypes. Furthermore, repeated ischemic subcortical strokes ultimately lead to vascular dementia, the second common cause of cognitive dysfunction in the elderly. Since demyelination and oligodendrocyte (OL) loss are prominent features of vascular dementia pathology, preventing demyelination and OL loss after ischemic subcortical white matter injury would be an important therapeutic strategy for the vascular dementia. We have developed a mouse model of white matter stroke in which endothelin-1 was stereotaxically injected into the posterior limb of internal capsule. In this model, a localized demyelinating lesion develops in the injection site, where activated macrophages are compacted. The macrophage infiltration was accompanied by the increased expression of proinflammatory cytokines. Toll-like receptor 2 (TLR2), the upstream modulator of innate immunity after ischemic stroke, was also increased in ischemic demyelinating lesion. Interestingly, the extent of demyelinating pathology was larger in TLR2 deficient mice than that of wild type animals. TLR2 (-/-) mice expressed more activated-caspase 3(+) OLs than wild type mice, although there was no difference of inflammatory cell infiltration into the ischemic lesion between TLR2 (-/-) and wild type mice. Phosphorylation of ERK 1/2, one of protective downstream signaling proteins of TLR2 was decreased in TLR2 (-/-) mice than wild type mice. We also found that cultured OLs obtained from TLR2 (-/-) animals were more vulnerable to oxygen-glucose deprivation (OGD) than that of wild type OLs *in vitro*. Applying Pam3CSK4, one of TLR2 agonist, after OGD in wild type OLs rescued OGD-induced OL death. These data demonstrated that TLR2 plays a protective role against ischemic demyelination and OL death, suggest modulation of TLR2 could be utilized as a novel therapeutic target to treat ischemic white matter stroke.

Title: Endogenous interferon-β modulates hallmarks of the inflammatory and immune response during the first week after ischemic stroke

Authors: *A. R. INACIO[1], Y. LIU[2], K. KUCHARZ[1], T. STANKOVICH[1], S. ISSAZADEH-NAVIKAS[2], T. DEIERBORG[1]
[1]Neurosurg., Lund Univ., Lund, Sweden; [2]Biotech Res. and Innovation Ctr. (BRIC), Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Ischemic stroke leads to the activation of a dynamic inflammatory and immune response, in and outside the brain. This response has been shown to critically affect neuronal death and functional recovery, and identification of underlying molecular and cellular determinants may prompt the development of stroke treatment. Interferon-β (IFN-β) is a potent immunomodulator, used in the treatment of the multiple sclerosis, an autoimmune disorder of the central nervous system. We aimed at determining if endogenous IFN-β influences (1) hallmarks of the inflammatory/immune response, (2) the extent of sensory-motor deficits and (3) neuronal death after ischemic stroke.
We subjected wild type (WT) and IFN-β knockout (IFN-β KO) mice, males, to transient middle cerebral artery occlusion (tMCAo) or sham-surgery. Populations of inflammatory and immune cells in the brain, blood and spleen were characterized using flow cytometry. We quantified the protein concentrations of T helper (Th)1 and Th2 cytokines in blood plasma using a multiplex immunoassay. Sensory-motor deficits were assessed by a modified composite neuroscore, the rotating pole and grip strength tests, and cerebral infarct volumes were given by lack of neuronal nuclei immunoreactivity. Samples were collected 2 and 8 days after surgery.
Abrogation of IFN-β in mice resulted in a higher number of $CD11b^{+}/CD45.2^{high}$ cells (putative macrophages) within the injured cerebral hemisphere 2 days after tMCAo. Concomitantly, we found a higher number of circulating $B220^{+}/MHCII^{+}$ cells (B cells) in IFN-β KO mice than in WT controls. Increases in splenic $B220^{+}/MHCII^{+}$ and $CD8^{+}/CD122^{+}$ cells occurred between 2 and 8 days after tMCAo in WT, but not in IFN-β KO mice. In addition, deletion of *Ifnβ* in mice resulted in decrease in spleen weight, as well as in the number of splenocytes (as observed in sham-operated mice), and a stroke-induced decrease in the number of splenocytes was not verified in IFN-β KO mice. Beyond alterations in the inflammatory and immune response at the

cellular level, we found an increase in interleukin (IL)-1β and IL-5 in IFN-β KO mice, also 2 days after tMCAo. Importantly, IFN-β KO mice showed less neurological deficits 24 h after tMCAo (composite neuroscore). However, we did not observe a significant difference in behavioral performance 2 and 7 days after tMCAo, using the grip strength and rotating pole tests. No difference was obtained with respect to infarct volumes 8 days after stroke.
Our results indicate that endogenous IFN-β, while being a critical regulator of the inflammatory and immune response, may not significantly contribute to functional recovery and neuronal death post-stroke.

Title: HCA_2-mediated protective effect of nicotinic acid in cerebral ischemia

Authors: M. RAHMAN[1], S. MUHAMMAD[1], J. G. OKUN[2], S. OFFERMANNS[3], *M. SCHWANINGER[1]
[1]Inst. of Exptl. and Clin. Pharmacol. and Toxicology, Univ. Luebeck, Luebeck, Germany; [2]Univ. of Heidelberg, Heidelberg, Germany; [3]Max-Planck-Institute for Heart and Lung Res., Bad Nauheim, Germany

Abstract: Nicotinic acid has been used as a lipid modifying drug since decades. The anti-lipolytic effect of nicotinic acid in adipocytes is mediated by the hydroxy-carboxylic acid receptor HCA_2 (GPR109A), a $G\alpha_i$-coupled receptor. In addition to adipocytes, immune competent cells express HCA_2. Cannabinoid receptor 2 (CB_2) is another $G\alpha_i$-coupled receptor expressed in immune cells and has been reported to be protective in ischemic stroke by inhibiting neutrophil recruitment. Therefore, in this study we hypothesized that nicotinic acid and its receptor HCA_2 might have an important role in the context of cerebral ischemia. When we subjected mice to distal permanent middle cerebral artery occlusion (pMCAO), treatment with nicotinic acid for 48 hours reduced the infarct volume. However, this protective effect was lost in $HCA_2^{-/-}$ mice demonstrating that HCA_2 mediates neuroprotection. As HCA_2 is significantly expressed in immune cells, we depleted CD11b-positive cells using CD11bDTR mice and subjected them to pMCAO. We noticed a loss of neuroprotection upon nicotinic acid treatment

indicating the involvement of microglia/macrophages. Moreover, flow cytometry revealed reduced number of activated microglia/macrophages in the ischemic brain tissue when treated with nicotinic acid, which was confirmed by immunostaining. We generated chimeric mice by bone marrow transplantation to sort out whether central or peripheral macrophages are involved. Wild-type mice as well as $HCA_2^{-/-}$ mice that received wild-type bone marrow were protected against cerebral ischemia when treated with nicotinic acid whereas the effect of nicotinic acid treatment was abolished when $HCA_2^{-/-}$ bone marrow was transplanted to wild-type mice confirming that bone marrow derived $CD11b^+$ cells are mediating the protective effect of nicotinic acid. Thus, we conclude that nicotinic acid is protective in cerebral ischemia and this effect is mediated by HCA_2 receptor present in peripheral $CD11b^+$ cells.

Title: Intranasal delivery of HMGB1-binding heptamer peptide confers robust neuroprotection in the postischemic brain

Authors: *I.-D. KIM, J.-H. SHIN, Y.-C. JIN, L. LUO, H.-K. LEE, J.-K. LEE
anatomy, Inha Univ., Inchon, Korea, Republic of

Abstract: Non-invasive intranasal drug administration enables direct drug delivery to the brain. In a previous study, we reported on the therapeutic efficacy of intranasal siRNA delivery in the postischemic rat brain. When siRNA for high mobility group box 1 (HMGB1), which functions as an endogenous danger molecule and aggravates inflammation, was delivered intranasally, expression of the target gene was found to be depleted in many brain regions and infarct volume to be suppressed by up to 42.8±5.6% at 48 hrs after 60 minutes of middle cerebral artery occlusion (MCAO). In the present study, we investigated the therapeutic efficacy of HMGB1 inhibitory heptamer peptide (HBHP; HMSKPVQ), a HMGB1-binding peptide selected using a phage display approach, in the same rat stroke model. Intranasal delivery of HBHP (300ng) at 60 minutes before MCAO suppressed infarct volume in the postischemic rat brain (maximal reduction to 58.8±4.5%) and ameliorated neurological and behavioral deficits. Furthermore, HBHP significantly suppressed HMGB1-mediated neuronal cell death in primary cortical

cultures. HBHP also dose-dependently suppressed HMGB1-mediated microglia activation. Binding experiments using biotin-labeled HBHP showed that HBHP binds directly to HMGB1, suggesting that this is responsible for inhibiting cytokine-like function of HMGB1. In contrast, a heptamer peptide composed of a scrambled sequence of the seven amino acids in HBHP had no protective effect or bond HMGB. Together these results suggest that intranasal delivery of HIHP ameliorates neuronal damage in the ischemic brain by inhibiting HMGB1.

Abstract: Mesenchymal stem cells (MSCs) have been shown to enhance the recovery of brain functions from the ischemic injury. In this study, we investigated the signaling molecules through which the grafted MSCs interact with damaged host brain and salvage the brain parenchyma from the secondary damages triggered by circulating immune cells. Transient occlusion of a middle cerebral artery induced the expression of proinflammatory cytokines such as MCP-1, TNFα, and IL-1β in the ischemic area. Transplantation of bone marrow-derived MSCs at postischemic day 3 reduced the expression of those cytokines and subsequent infiltration of invasive immune cells to the ischemic area. *In vitro* studies with anti-MCP-1 antibody indicated that MCP-1 in ischemic brain extracts was primary signaling molecule that chemoattracted peritoneal macrophages. The MSC-conditioned could also block both MCP-1 expression and immune cell migration. The results suggest that immunomodulatory functions of MSCs are mediated through downregulation of MCP-1 expression.

Title: Temporal window of protection by splenectomy against experimental stroke

Authors: *M. A. YENARI[1], X. TANG[1], C. HSIEH[2], M. NAKAMURA[2]
[1]Neurol, [2]Med., Univ. California, San Francisco and San Francisco Veterans Affairs Med. Ctr., San Francisco, CA

Abstract: Immune responses play a pivotal role in protecting and worsening ischemic injury. The spleen is the largest lymphoid organ of the body, and is the site where many acquired immune responses occur, such as antigen presentation, complement opsonization and other functions. Prior work has shown dramatic splenic atrophy and protective effects of splenectomy on outcome from experimental stroke. Here, we attempt to define the temporal therapeutic window for splenectomy and neuroprotection against brain ischema. We used an intraluminal filament model to occlude the middle cerebral artery (MCAO) for 1h followed by 22h reperfusion. 38 male C57BL/6 mice were randomly divided into 5 groups: sham splenectomy+MCAO, spelenectomy performed 1, 3, 7 or 14d prior to MCAO. Compared to mice receiving sham splenectomy, infarct size was decreased among mice receiving spelenectomy 1d prior to MCAO (130.00±7.43 mm3 vs 80.10±9.79 mm3, $p<0.05$), while mice receiving splenectomy 3 or 7d prior showed a trend towards increased infarct size (splenectomy 3d before MCAO: 130.00±7.43 mm3 vs 162.45±15.39 mm3; splenectomy 7d before MCAO: 130.00±7.43 mm3 vs 160.79±7.1690 mm3) and no effect was observed when splenectomy was performed 14d earlier. A pilot group of 3 mice were also studied where splenectomy was carried out post MCAO and at the time of reperfusion, but all animals died before 24h. We then studied an additional 9 mice to determine leukocyte counts and phenotype in the brain for MCAO only, sham splenectomy plus MCAO, and splenectomy carried out 1d prior to MCAO, and splenectomy but no MCAO (n=3/ group). Leukocytes from the brain parenchyma were harvest using a density-gradient centrifugation technique. Cells were stained with the following

fluorescence-tagged antibodies: anti-CD45 APC (clone Ly5) (eBioscience), anti-CD11b (clone M1/70) PE (Invitrogen) or PE-Cy5 (eBioscience), anti-Ly6G (clone 1A8) PE-Cy7 (BD Biosciences) and sytox blue. After incubation, cells were sorted by FACS machine. There was no statistical difference between MCAO only and sham splenectomy plus MCAO, but numbers of circulating monocytes was decreased by ~50% in animals receiving splenectomy 1d prior to MCAO. We show that splenectomy protects only when carried out 1d prior to MCAO, and is associated with reduced monocyte infiltration into the ischemia brain. These observations expand prior studies showing the neuroprotective effects of splenectomy. The defined time window for such an effect may provide insight into potential mechanisms.

Title: Live imaging of innate immune response: Chronic estrogen deprivation alters microglia activation profiles after stroke.

Authors: *P. CORDEAU JR[1], Y. WENG[2], J. KRIZ*[2]
[1]Anat. and Physiol., Laval Univ., quebec, QC, Canada; [2]CHUL, Québec, QC, Canada

Abstract: Background: Our previous study employing live imaging analysis of neuroinflammatory signals revealed a marked gender difference in astrocyte response to ischemic injury. However, the effects of estrogens (gender) on microglia activation profiles after stroke remain unclear. Microglia are critical for proper innate immune responses in the brain since they are responsible for orchestration of the injury-induced inflammation, the processes that may significantly affect evolution of the ischemic injury. To date, the role of estrogens in the modulation of the post stroke innate immunity is far from being elucidated. On those bases, the in vivo study of the microglial responses/TLR2 signal induction in ovariectomized and control mice could bring some light on the mechanism affecting the stroke evolution.
Methods: The TLR2-Luc-GFP, TLR2-Luc-GFP x ErαKO and TLR2 x ErβKO mice were subjected to middle cerebral artery occlusion (MCAO) after a deprivation of estrogens of 14 or 40 days and compared to adequate controls. The pattern and the intensity of the TLR2 signals were longitudinally monitored using in vivo biophotonic/bioluminescence imaging.

Results: In all groups a marked upregulation of the TLR2 signal was detected post MCAO. Interestingly, we did not observed significant difference in TLR2 induction between control male and female mice. However, our results revealed a significant difference in the signals measured before and after the MCAO in the group chronically deprived of estrogens. The chronic estrogen deprivation was associated with significant increase in post-ischemic microglial activation and larger infarct lesions. The increase in TLR2 signals was blunted in ErαKO.
Conclusions: The TLR2 reporter mouse represents a valid model to study microglia activation in ischemic brain of live animals after chronic or acute estrogens deprivation. Furthermore, the receptor Erα seems to be needed for TLR2 activation after MCAO. Further studies are needed to better understand a complex relationship between the inflammation, estrogens and brain recovery.

Title: Chemokine receptor CXCR4 antagonism improves functional recovery after stroke

Authors: K. RUSCHER[1], E. KURIC[1], A. INACIO[1], Y. LIU[2], S. ISSAZADEH-NAVIKAS[2], E. ENGLUND[1], *T. W. WIELOCH[1]
[1]Lund Univ., Lund, Sweden; [2]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Inflammation in the ischemic hemisphere hampers brain tissue reorganization and functional recovery after stroke. Here, we show that rats housed in enriched environment (EE) dramatically improves recovery of lost neurological functions after experimental stroke induced by permanent occlusion of the middle cerebral artery (pMCAO). Enriched environment profoundly attenuated levels of pro-inflammatory cytokines in the ischemic core and the surrounding peri-infarct area. We also observed a significant reduction in the stroke-induced chemokine receptor CXCR4 and its natural ligand stromal cell-derived factor-1 (CXCL12). The receptor was also increased in the brains of stroke patients. To mimic the beneficial effects of EE, we studied the impact of inhibiting CXCL12/CXCR4 on functional recovery after transient

MCAO (tMCAO). Rats treated with the specific CXCR4 antagonist 1-[4-(1,4,8,11-Tetrazacyclotetradec-1-ylmethyl)phenyl]methyl]-1,4,8,11-tetrazacyclo-tetradecan (AMD3100) showed improved recovery compared to saline-treated rats after tMCAO. Enhanced recovery was accompanied by a reduction in infiltrating immune cells in the ischemic territory, particularly CD3+ and CD3+/CD4+ T cells. Splenatrophy and delayed death of splenocytes, seen after tMCAO, was prevented by AMD3100 treatment. However, AMD3100 treatment did not affect the number of circulating lymphocyte and the number of circulating CD34 positive progenitor cells 6 days after tMCAO. We conclude that the CXCL12/CXCR4 pathway contributes to depression of neurological function after stroke and that its inhibition is beneficial and may become an attractive stroke therapy.

Title: Levodopa treatment attenuates inflammation and improves functional recovery after experimental stroke

Authors: E. KURIC, T. WIELOCH, *K. RUSCHER
Univ. of Lund, Lund, Sweden

Abstract: Delayed treatment of stroke patients with levodopa/benserazide contributes to enhanced functional recovery, but the mechanisms involved are poorly understood. The present study was designed to investigate if L-Dopa/benserazide treatment improves recovery of lost neurological function in rats by affecting the inflammatory response in the ischemic hemisphere. We subjected male Wistar rats to transient occlusion of the middle cerebral artery (tMCAO, 120min) and treated animals with levodopa (1, 5 and 20 mg/kg)/benserazide (15mg/kg) or saline for 12 consecutive days starting on day two after tMCAO. Thereafter, infarct volume was determined and sensorimotor function was assessed using the cylinder test, the rotating pole test and a 28 points neuroscore on day 2, 7 and 14 after tMCAO. The ischemic core and adjacent

peri-infarct area were dissected and pro-inflammatory cytokines were measured in different areas of the ischemic hemisphere to estimate the poststroke inflammatory response.
Our data show that treatment with levodopa/benserazide significantly improves recovery of sensorimotor function following tMCAO assessed by multiple behavioral tests without affecting the infarct volume. We also observed that levodopa significantly reduced the levels of interleukin-1beta and interferon-gamma in the infarct core and adjacent peri-infarct area on day 14 after tMCAO. Concomitantly, expression of dopamine receptors on inflammatory cells such as microglia/macrophages indicate their susceptibility to treatment.
After stroke, levodopa treatment affects cellular and molecular processes which improve recovery of lost neurological function. The present study corroborates that levodopa contributes to the inhibition of inflammatory processes in the ischemic hemisphere.

Title: $CD4^+$ T helper cell infiltration in the AV3V region and frontal cortex is associated with hypertension in response to placental ischemia in pregnant rats

Authors: *K. L. WALLACE, M. DARBY, J. MOSELEY, B. LAMARCA
Univ. MS Med. Ctr., JACKSON, MS

Abstract: INTRODUCTION. We have previously shown that a reduction in uterine perfusion pressure (RUPP) causes hypertension, elevations in circulating inflammatory cytokines and in agonistic autoantibodies to the angiotensin II receptor and activation of $CD4^+$ T helper cells in the circulation of Sprague Dawley rats. Furthermore, we have also shown that adoptive transfer of $CD4^+$ T cells from RUPP rats into normal pregnant (NP) rats also causes hypertension and increases these same inflammatory mediators. The central nervous system plays an important

role in the pathogenesis of hypertension and neuronal ischemia and inflammation is associated with the development of hypertension during preeclampsia. Therefore we hypothesize that hypertension in response to chronic placental ischemia stimulates $CD4^+$ T cells infiltration into the central nervous system.
METHODS. Sprague Dawley rats were anesthetized on gestational day (GD) 14 of pregnancy and underwent either examination under anesthesia (NP) or had the lower abdominal aorta above the iliac bifurcation chronically constricted (0.203mm ID clip) along with both ovarian arteries (0.100mm ID clip). On GD18 rats were instrumented with a carotid catheter for arterial pressure measurement (MAP). We measured MAP and circulating T cells on GD19 in NP and placental ischemic pregnant RUPP rats. We utilized flow cytometry to analyze $CD4^+$ T cells from RUPP and NP plasma. Maternal brains were collected at the time of sacrifice and processed for histological analysis for CD4 expression.
RESULTS: MAP increased from 96.2 $\pm$ 3.6mmHg (n=5) in NP rats to 127.8 $\pm$ 3.8mmHg (n=5; p=0.0003) in RUPP rats. $CD4^+$ T cells increased to 48.69 $\pm$ 2.8% gated (n=3) in RUPP rats compared to 24.35 $\pm$ 2.5% gated (n=4; p=0.001) in NP rats. After staining with cresyl violet, brains from RUPP rats had darker neurons, representative of neuron injury and analysis revealed a disorganized cytoarchitecture when compared to brains from NP rats. Additionally, there were more infiltrated $CD4^+$ T cells in the AV3V region and along the corpus callosum in RUPP brains compared to NP rat brains.
CONCLUSION.These data indicate that $CD4^+$ T cells are increased in response to placental ischemia in both the circulation and in regions of the brain and may therefore be one potential link in the neuropathophysiology of hypertension associated with preeclampsia.

Title: Regulation of Macrophage migration inhibitory factor (MIF) expression by NF-κB signaling

Authors: *S. F. ZHANG, O. ZIS, W. SONG
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Macrophage migration inhibition factor (MIF) is a pleiotropic protein expressed in various cell types and involved in many cellular activities. Our lab has previously demonstrated that MIF gene expression was elevated following cerebral ischemia through the hypoxia signaling pathway. Although the role of MIF during ischemic insult remains exclusive, it is of interest to explore other signaling pathways that can regulate MIF gene expression. NF-κB, a transcriptional factor, has been shown to be activated after stroke. Analysis of the promoter region of MIF gene reveals several putative NF-κB consensus binding sites. Therefore, we investigated whether NF-κB could also regulate the transcription of MIF. Using luciferase as the reporter gene, we demonstrated that MIF promoter activity was upregulated by NF-κB signaling activation. In addition, using gel shift and super shift assay, we demonstrated the binding between NF-κB and the putative consensus binding sites of NF-κB on MIF promoter. Moreover, we observed upregulation of MIF mRNA upon NF-κB signaling activation. Simultaneous upregulation of MIF and NF-κB was also observed in the protein level. Finally, we showed that MIF level in mouse brain was elevated after ischemic insult. The results of the current results suggested NF-κB can enhance the expression of MIF gene under ischemic insult.

Title: Cell adhesions affect neuronal injury in a model of mild traumatic brain injury.

Authors: *M. A. HEMPHILL, J. A. GOSS, B. E. DABIRI, K. K. PARKER
Sch. of Engin. and Applied Sci., Harvard Univ., CAMBRIDGE, MA

Abstract: Blast-induced Traumatic Brain Injury has been called the signature wound of the Afghanistan and Iraq wars and has underscored the current limitations in treating this disease. Mild Traumatic Brain Injury (mTBI) has presented a unique challenge in that there is a lack of

mechanistic understanding of the processes which initiate neuronal injury. Previous reports have shown that a mechanical insult can rupture the cell membrane and initiate injurious signaling cascades, but this mechanism cannot account for all injured neurons. Cells can transduce extracellular mechanical signals directed through adhesion complexes into normal remodeling signals. We hypothesize that injury forces transmitted through adhesion complexes in the cell membrane may initiate remodeling pathways in a pathological manner which can account for injury in neurons following mTBI

To study this, we built two in vitro devices which allowed us to deliver mechanical stimuli to a population of neurons through specific cell adhesions. First, primary cortical neurons from neonatal sprague-dawley rats were seeded on stretchable membranes coated with adhesion proteins poly-l-lysine (PLL) or fibronectin (Fn) and cultured for 5 days in 10% serum supplemented media. A single, high speed stretch (1 % per ms) to a specific magnitude was administered to mimic mTBI. In the second model, 4.5 μm ferromagnetic beads were coated with the same adhesion proteins and bound to neurons seeded on PLL coated substrates. A brief magnetic pulse was applied generating a force on the adhesion between neuron and bead

We found that neurons subjected to a single rapid stretch exhibited neurite focal swelling, similar to that observed in axons following TBI, that was strain magnitude dependent. Furthermore, the extent of injury at a given magnitude was found to be dependent upon the adhesion protein at 10 minutes following injury, but not at 60 minutes. Neurons which were subjected to bead twisting forces also exhibited magnitude and adhesion coating dependent injury levels. Interestingly, in these experiments we observed that neurons coated with FN coated beads exhibited injury onset at earlier time points than neurons coated with PLL, however, by 60 minutes the extent of injury was similar.

These results indicate that the type of adhesion though which a mechanical stimulus is transmitted may affect the extent of neuronal injury. Since the adhesion type appears to alter the injury initiation time, it is possible that it also affects the mechanism of injury. Future studies are necessary to further elucidate the injury mechanisms underlying neuronal injury following mTBI.

Title: Altered expression of injury response mediators after TBI in juvenile rats with decreased brain omega-3 DHA content

Authors: *K. L. RUSSELL[1], N. E. J. BERMAN[2], B. LEVANT[3]
[1]Pharmacology, Toxicology & Therapeut., [2]Anat. & Cell Biol., [3]Pharmacology, Toxicology, & Therapeut., Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Children under 5 years of age are at high risk for sustaining traumatic brain injuries (TBI) and tend to have poorer outcomes despite the greater neuroplasticity in children. N-3 (omega-3) polyunsaturated fatty acids (PUFA) are a major component of neural membranes and have multiple neuroprotective and anti-inflammatory activities. These fatty acids, of which docosahexaenoic acid (DHA) is the major species in brain, accumulate in the brain during late gestation and early childhood. Low dietary N-3 PUFA content results in decreased DHA accumulation in the developing brain. We have previously shown that juvenile rats with a large decrease in brain DHA level (-54%) have poorer sensorimotor outcomes after TBI. Accordingly, this study examined the effects of dietary modulation of brain DHA content on molecular outcomes after TBI in a juvenile rat model. Two sequential litters of male, Long-Evans rats (n=5-13/group) were raised from conception on diets containing adequate n-3 PUFA (N-3) or low in n-3 PUFA (Low N-3). First and second litter rats raised on the Low N-3 diet had decreases in brain DHA of 25% and 54%, respectively, compared to rats raised on the N-3 diet. On postnatal day 17, rats received a unilateral controlled cortical impact injury to the sensorimotor cortex or a sham surgery. The sham surgery consisted of scalpel incision but no craniotomy. Expression of genes associated with inflammation and blood brain barrier disruption were measured via real-time PCR 1 and 7 days after surgery. Monocyte chemotactic protein-1 (Mcp-1) and glial fibrillary acidic protein (Gfap), markers of inflammation and microglial activation, and matrix metalloproteinase-9 (Mmp-9), a mediator of blood-brain barrier disruption, were increased after TBI regardless of brain DHA level. In contrast, tissue inhibitor of metalloproteinase-1 (Timp-1), had increased expression after TBI, but the increase in Timp-1, was smaller in rats with lower brain DHA levels. Besides inhibiting MMP-9, TIMP-1 also acts as an anti-apoptotic and survival factor, indicating altered expression of this gene may play an important role in the extent of secondary damage after TBI. This suggests that altered expression

of injury response mediators in rats with low brain DHA rats may contribute to the previously observed worsened behavioral outcomes after TBI.

Title: Long-term effects of traumatic brain injury on the prefrontal cortex: tau alterations and cognitive dysfunction

Authors: *L. NAVARRIA, JR[1,2], J. MORGANTI[1], A. ALLEN[1], K. BELARBI[1], E. CUELLAR[1], T. JOPSON[1], J. FIKE[1], S. ROSI[1]

Abstract: Traumatic brain injury (TBI) is a major risk factor for the development of multiple neurodegenerative diseases, such as Alzheimer's disease and frontotemporal dementia. Patients with TBI often suffer from deficits in working memory function related to prefrontal cortex (PFC) and show macroscopic abnormalities in this region. Additionally, human studies have shown aggregation of the neuronal microtubule-associated protein tau in the post mortem brains from long-term survivors of a single TBI. Tau stabilizes and promotes microtubule polymerization and its alteration is involved in multiple neurodegenerative disorders. Post-translational modifications of tau such as hyperphosphorylation and/or cleavage reduce its ability to bind microtubules, leading to a loss of function and its progressive pathological accumulation. In the present study we examined changes tau (phosphorilation and cleavage) and cognition in the PFC long time following TBI in young (2 month) and old (16 month) C57BL/6J male mice. Briefly, mice received a unilateral cortical contusion to the right parietal cortex using a controlled cortical impact. Two months after TBI or sham surgery, PFC-related cognitive function was assessed using reversal learning radial arm water maze (RAWM). The test revealed a significant impairment in young animals that received TBI relative to the respective sham operated animals. Quantitative western blot analysis for tau and its multiple phosphorylated sites

was performed using AT8, pSer396 and tau-1 antibodies. TBI induced significant hyperphosphorylation of tau in the ipsilateral PFC of young mice relative to sham. Furtheremore, TBI induced the appearance of a small c-terminal derived tau fragment in the PFC of both young and old mice not apparent in sham mice. Interestingly, there was a direct correlation between the level of phorphorilated tau and the cognitive performances.
Our data demonstrate for the first time that TBI can induce post-translational modifications of tau and suggests these changes could have a crucial role in the development of TBI-induced cognitive dysfunctions associated with the PFC. Further characterization of the alterations of tau following TBI may provide a basis for pharmacological interventions as a viable treatment to prevent cognitive decline.

Title: Conditional knock out of beta-catenin in GFAP-expressing cells reduces GFAP-positive cell proliferation and immature neuron numbers after traumatic brain injury

Authors: *D. M. SAMA[1], S. K. MADATHIL[2], J. CHEN[3], K. E. SAATMAN[2]
[1]Spinal Cord and Brain Injury Res. Ctr., [2]Dept. of Physiol. and Spinal Cord and Brain Injury Res. Ctr., Univ. of Kentucky, LEXINGTON, KY; [3]Dept. of Neurolog. Surgery and Stark Neurosciences Res. Inst., Indiana Univ., Indianapolis, IN

Abstract: β-catenin, known for its role in mediating the canonical Wnt signaling pathway and cell-cell interaction, can influence cell proliferation and differentiation. Astrocyte and neural progenitor cell (NPC) division rely on β-catenin, as does NPC differentiation into additional NPCs, new neurons, or new astrocytes. These cell populations are profoundly affected by traumatic brain injury (TBI) induced using a controlled cortical impact (CCI) model. CCI initially results in a dramatic loss of immature neurons while stimulating a delayed proliferation of NPCs and astrocytes, both of which stain positively for glial fibrillary acidic protein (GFAP). We hypothesize that β-catenin signaling is critical for both astrocyte and NPC proliferation following CCI. The present experiments utilize a novel transgenic mouse (cat-cKO) in which β-catenin signaling is conditionally knocked out in GFAP-expressing cells using the Cre-lox system, thereby affecting NPCs and astrocytes. Adult mice were injected with bromodeoxyuridine (BrdU) 4h prior to euthanasia at 72h post-injury, to label dividing cells at a time point of peak hippocampal proliferation. Dual immunofluorescent labeling for BrdU and cell-specific markers was used to identify cell phenotype. GFAP-positive (GFAP+) cell proliferation typically increases by 72h following CCI, while immature neuron numbers decrease. Our results confirm increased GFAP+ cell proliferation in wild-type (WT) mice (n=5) at 72h, while cat-cKO mice (n=6) show significantly less GFAP+ proliferation. The total number of immature neurons is also less in cat-cKO mice compared to WT mice at 72h, presumably due to decreased NPC proliferation and differentiation. Because microglial lineage is distinct from GFAP+ NPCs and astrocytes, microglial proliferation was examined as a control in the cat-cKO mice. Unexpectedly, compared to WT, cat-cKO mice show a decrease in microglial proliferation 72h post-CCI. We therefore examined a second cohort of TBI-injured animals, injected with BrdU 4h prior to euthanasia at 48h, a time at which there is minimal GFAP+ cell proliferation, but robust microglial proliferation. At 48h post-CCI, there is no effect of the cat-cKO (n=4) on microglial proliferation compared to WT mice (n=5), confirming the specificity of the GFAP-linked deletion, while also suggesting that proliferating GFAP+ cells participate in a feedback loop to enhance microglial proliferation. Future studies will explore downstream effects of β-catenin-dependent GFAP+ cell proliferation on neurodegeneration, synaptic/cognitive alterations, and blood-brain barrier integrity following trauma.

Title: Tracking neuroprogenitor cells and mesenchymal stem cells following traumatic brain injury.

Authors: *A. DARKAZALLI[1,2], T. J. MORGAN[2], J. T. ROSENBERG[3], M. MUROSKI[4], G. STROUSE[4], S. C. GRANT[3], C. W. LEVENSON[2]

Abstract: Stem cell-mediated therapies have a great deal of potential for the treatment of traumatic brain injury (TBI). We are developing novel magnetic resonance imaging (MRI)-based techniques to track the migration and fate of both endogenous stem cells that arise from the subventricular zone (SVZ) as well as mesenchymal stem cells (MSC) administered after TBI. Previous work has shown that neuroprogenitor cells residing in the SVZ are capable of endocytosing superparamagnetic iron oxide particles (SPIO) that can be tracked by MRI in vivo as they migrate along the rostral migratory stream (RMS). We have now shown that a similar approach can be used to monitor the migration of these cells to the site of TBI. Furthermore, our ability to track these cells at high resolution is enhanced by our use of ultra-high field MRI (900, MHz, 21.1Tesla) in vivo. Using this technology to track rodent and human bone marrow-derived MSC is facilitated by the intrinsic ability of these stem cells to migrate to lesions resulting from a wide variety of brain injury and disease. After receiving a TBI via controlled cortical impact, rats received an intra-carotid injection of 3x106 SPIO-labeled MSC which were localized by in vivo MRI to the penumbral region 48 h post-injury. No labeled cells were detected outside of this region of the brain. We have further refined our tracking ability by modification of fluorescent quantum dots with cell penetrating peptides to facilitate uptake by MSC as well as gene constructs designed to enhance both survival and tracking. Histological analysis confirmed MRI data showing migration of MSC to the penumbral region. Because this region that surrounds the site of injury is susceptible to secondary cell death, we are tracking the fate of these cells both temporally and phenotypically. Thus, these advances constitute a valuable tool for assessing the behavior of stem cells in preclinical models of brain injury and other models of neurodegenerative disease.

Title: Alterations in neuronal-glial metabolic coupling following lateral fluid percussion injury

Authors: *J. M. SEE[1], J. ELKIND[1], O. HORYN[2], I. NISSIM[2], E. DAIKHIN[2], I. NISSIM[2], A. COHEN[1]
[1]Pediatric Neurol., [2]Child Develop., Children's Hosp. of Philadelphia, PHILADELPHIA, PA

Abstract: Traumatic brain injury (TBI) often causes enduring disabilities including cognitive impairment and memory dysfunction. These functional deficits result from changes in hippocampal network excitability due to imbalances between excitatory and inhibitory synaptic activity, including decreased network excitability in CA1 and increased net synaptic efficacy in the dentate gyrus. Furthermore, neuronal and astrocyte metabolism following injury are altered, including increased accumulation of lactate and an increase in intracellular glutamate, but the interaction between astrocyte-derived metabolites and neuronal metabolism following injury is unclear. Thus, the purpose of this study is to investigate the changes in metabolic interactions between glia and neurons following injury. We have investigated the effects of fluid percussion injury (FPI) on cellular metabolism in hippocampus by treating hippocampal slices from injured and sham mice with 13C-labeled metabolic substrates, using 13C-acetate to specifically examine changes in astrocyte metabolism and 13C-glucose to investigate non-cell type specific metabolic changes. Samples were then analyzed to determine whether injury alters neurotransmitter production, amino acid metabolism or organic acid production. Previous data have shown that treatment with branched-chain amino acids (BCAAs) leads to improved functional recovery following injury, so we have also investigated the effects of BCAA treatment on hippocampal metabolism. Total neurotransmitter and amino acid concentrations are unchanged by injury, and acetate-derived 13C enrichment of aspartate and glutamate was also unchanged following FPI. Interestingly, acetate-derived 13C GABA and 13C glutamine enrichment are increased following FPI, suggesting that neuronal metabolism from glial-derived metabolites is augmented following injury. Addition of BCAAs returns GABA and glutamine enrichment to normal. To investigate the effects of hippocampal FPI on glucose metabolism, we incubated slices with 13C glucose and determined amino acid and neurotransmitter enrichment, finding that BCAA treatment alters glucose derived 13C incorporation into glutamate, aspartate, and alanine. These experiments suggest that changes in coupling of neuronal and glial metabolism may underlie and contribute to changes in excitability following TBI and that BCAA treatment mitigates these changes thus

indicating a possible mechanism underlying previously observed improvements in functional recovery.

Title: Chronic Pain after TBI: Thalamic abnormalities and prophylaxis with glyburide

Authors: *A. S. PARIHAR[1,2], M. J. SIMARD[2], K. KELEDJIAN[2], V. GERZANICH[2], A. KELLER[1]
[1]Anat. and Neurobio., [2]Neurosurg., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: In the US alone, about 1.4 million people suffer from traumatic brain injury (TBI) every year. TBI is an important health issue in both military and civilian life, and is very common among war-fighters. About one half of these individuals suffer not only from cognitive and motor deficits, but also from excruciating, unrelenting and chronic pain. In the current study, we aim to understand the mechanisms that lead from brain trauma to the development of chronic pain. We also explore the prophylactic potential of glyburide (GLY) to prevent the development of this devastating condition. The mechanisms of chronic headaches in general, and post-TBI pain in particular, are largely unknown. Considerable evidence, from both human and animal studies, indicates that this is the result of “central sensitization”, a process by which brain structures undergo maladaptive plasticity, resulting in abnormal activity of brain neurons. We have recently demonstrated that after spinal cord injury (SCI), such central sensitization occurs in the posterior thalamus (PO). Here, we test the hypothesis that TBI-Pain results in changes in PO similar to those after SCI. Testing for mechanical hyperalgesia revealed that TBI-Pain rats have a significantly lower tolerance to pain compared to the control group, and to TBI-Pain rats that received GLY. GLY (infusion of 200 ng/h of GLY yields plasma concentrations ~ 5 ng/ml, this has a minimal effect on serum glucose) was administered through mini-osmotic pumps implanted subcutaneously immediately after TBI surgery. Consistent with the behavioral data,

single unit electrophysiological recordings from the PO showed an increase in the spontaneous firing rate of neurons from TBI-Pain rats, compared to sham. Furthermore, histology from TBI-Pain rats revealed upregulation of SUR-1-regulated NCCA-ATP channel (molecular target for GLY), GFAP (astrocytic marker), and Iba1 (marker for microglial activation) in the thalamus of TBI-Pain rats. These data support the hypothesis that TBI-Pain is associated with maladaptive plasticity in the PO thalamus and that prophylactic treatment with GLY prevents TBI-Pain.

Title: Detrimental neuroinflammatory response following TBI is mediated by microglia via p38α MAPK dependent mechanism

Authors: *A. D. BACHSTETTER[1], R. ROWE[2,3], B. XING[1], M. KANEKO[1], J. LIFSHITZ[2,3], L. J. VAN ELDIK, PhD[1,2]

Abstract: Neuropathologic damage following traumatic brain injury (TBI) is the result of both the immediate impact injury and secondary injury mechanisms. Post-traumatic glial activation with increased production of inflammatory molecules such as proinflammatory cytokines is a secondary injury mechanism that contributes to pathology progression in both animal models and human head injury patients. Moreover, following TBI the inflammatory response can result in persistently sensitized, or “primed” microglia, which can contribute to a chronic state of neuroinflammation. We recently demonstrated using in vitro models that p38α MAPK signaling in microglia is a key event in promoting cytokine production in response to diverse disease-

relevant stressors and subsequent inflammatory neuronal dysfunction. From these findings, we hypothesized that the p38α MAPK signaling pathway in microglia could be contributing to the secondary neuropathologic sequelae following a diffuse TBI. To test this hypothesis, we used a midline fluid percussion model to induce a diffuse brain injury in young adult wild-type (WT) mice or in conditional knockout mice genetically deficient in microglia p38α MAPK (p38α KO). From day 1-7 post-injury, motor coordination and balance were tested using a rotarod task. Injured WT mice showed a significant impairment on the rotarod task compared to sham-injured mice, while p38α MAPK deficiency in microglia prevented this TBI-induced impairment. Microglial activation was assessed by immunohistochemistry for three different microglial markers: IBA-1, CD45 and CD68. Mechanistically, we found that p38α MAPK was critical for microglia activation, as the p38α KO mice showed a dramatically reduced microglial activation response to the injury compared to the WT mice. The results suggest that stressor-induced activation of p38α MAPK signaling in microglia is a key event that primes microglia and leads to motor deficits following a diffuse TBI.

Title: Theta burst filtering by the dentate gyrus is diminished by brain injury and reinstated following treatment with branched chain amino acids.

Authors: J. WASSERMAN[1,2], B. N. JOHNSON[1], J. A. ELKIND[1], G. XIONG[1], *A. S. COHEN[1,2]
[1]Div. Neurosci, Children's Hosp Philadelphia, PHILADELPHIA, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The dentate gyrus (DG) filters afferent input from the entorhinal cortex, and plays a pivotal role in preventing the spread of hyperactivity to area CA3. The ability of the DG to function as a filter requires particular and localized inhibition across microcircuits of the

hippocampal network, and is not well understood (Hsu 2007), but could provide new therapeutic targets for the reduced seizure threshold caused by traumatic brain injury (TBI). One of the ways in which TBI decreases inhibitory efficacy within dentate granule cells is by eroding the chloride gradient necessary for robust inhibition (Bonislawski et al., 2007). The resulting decrease in the driving force for GABAergic currents may explain why the increased frequency of mEPSCs and action potentials of GABAergic hilar inhibitory neurons after TBI has little effect on the overall excitability of granule cells (Hunt et al., 2011).
Systemic and *in vitro [[Unsupported Character - Codename]]*treatment with branched chain amino acids, which are precursors for *de-novo[[Unsupported Character - Codename]]* synthesis of glutamate and GABA, restores DG network excitability in slices from brain injured animals to levels recorded in slices from sham animals. Using later Fluid Percussion Injury (lFPI) together with voltage sensitive dye imaging we assessed the spatial and temporal dynamics of filtering efficacy in the dentate gyrus seven days post injury. We found that treatment with BCAAs restored normal excitability of the molecular layer and normal filtering of the propagated activity to the hilus following theta burst stimulation of the perforant path. Interestingly, depolarization in the hilus reached a plateau after the first theta burst event. Further experiments will aim to characterize the origin of this restored inhibitory efficacy following BCAA treatment and perhaps give insight into hilar area-mediated inhibition of cortical input into the dentate gyrus.

Title: Regulation of antigen presention in cerebral cortex following traumatic brain injury

Authors: *C. ISRAELSSON, A. KYLBERG, L. T. HILLERED, T. EBENDAL
Dept. Neuroscience, Uppsala Univ., Uppsala, Sweden

Abstract: A unique and significant increase in the histocompatibility complex type II *H2-Aa* transcript was identified by unbiased analysis of cerebral cortex in response to traumatic brain injury using a mouse controlled cortical impact model (CCI). The indicated increase in MHC II antigen presentation made us turn to isolation of dendritic cell populations from neocortex three days after injury using anti-CD11c and anti-PDCA-1 antibodies coupled to magnetic beads. The results from qRT-PCR examination of this material directly link *H2-Aa* expression to CD11c/*Itgax*-positive conventional dendritic cells in the injured mouse brain. In order to suppress the increase of plasmacytoid dendritic cells in the injured mouse brain, we also administered antibodies directed against PDCA-1/*Bst2* positive cells. A significant reduction of the *Cxcl10* transcript was seen in the injured neocortex in mice receiving the anti-PDCA-1 antibodies compared to mice given equal doses of normal rat immunoglobulin. The results indicate that expression of the *Cxcl10* chemokine induced by injury, directly or indirectly depends on the presence of plasmacytoid dendritic cells. In contrast, expression of the *H2-Aa* transcript was induced to the same extent in the injured neocortex irrespective of the injected antibodies. This shows that the *H2-Aa* is not associated with the level of plasmacytoid PDCA-1 dendritic cells. Further cell types involved in injury responses were detected by *in situ* hybridization, demonstrating *Lyz2* expression in large phagocytic cells that also exhibited the cell surface marker isolectin B4 (IB4). In addition, small activated microglia were positive for IB4 in the injured neocortex and hippocampus three days post-injury but did not express *Lyz2*. The injury-induced cortical cavity formation was significantly reduced in *Ccr2*-/- mice seven days after injury in accordance with a reduction of *Lyz2*, adding support to the notion that *Ccr2* is a key receptor in recruitment of different invading peripheral cells. The importance of leukocyte invasion and activation in the development of antigen-presentation post-injury was confirmed by administration of cyclophosphamide to injured mice resulting in strong and selective reduction in several inflammatory-related transcripts e.g. *Ccr2*, *H2-Aa*, *Itgax* and *Bst2*. In contrast, *Cx3cr1* and *Ccl3* transcripts associated with resident microglia, were not affected. The data clearly demonstrate distinct functions of invading inflammatory cells of monocytic lineage separated from the roles of activated resident microglia.

Title: Inhibitory neurons in specific regions of CA1 are affected differently by injury and vary in their sensitivity to Branched Chain Amino Acids

Authors: *B. N. JOHNSON[1], E. BOURGEOIS[1], J. WASSERMAN[1,2], J. A. ELKIND[1], G. XIONG[1], A. S. COHEN[1,2]
[1]Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neurological impairments associated with TBI include deficits in learning and memory and a reduction in seizure threshold. The hippocampus is critically involved in both of these phenomena, and is susceptible to damage from traumatic brain injury. In TBI, as in epilepsy and other CNS disorders, the balance between excitation and inhibition is disrupted. In the hippocampus, area CA1 becomes less excitable, while the DG becomes more excitable. The balance between inhibition and excitation in a network of neurons is set through a combination of synaptic and non-synaptic means. We focus here on the synaptic component, and on the decreased network excitability in area CA1. Previous work in our laboratory showed increased inhibition within CA1 after injury, which could be reduced to normal levels by treatment with branched chain amino acids (BCAAs), key precursors in the *de novo* synthesis of glutamate and GABA.

In order to identify the source of inhibition we characterized the spatial and temporal dynamics within the circuit by combining voltage sensitive dye imaging with simultaneous field recordings. Although we did find injury-induced decreases in both field potential and VSD signals when stimulating the Schaffer Collaterals in control aCSF, these diminished signals were NOT restored to normal by treatment with BCAAs. We also did not observe any obvious changes in inhibition, either with Schaffer collateral stimulation, or when stimulating in the alveus to directly activate interneurons in the oriens and cell body layer. We repeated these experiments in APV and CNQX in order to isolate inhibitory responses, and found a significant increase in hyperpolarization in the oriens when the stratum radiatum was stimulated, but no differences in oriens hyperpolarization when the alveus was stimulated. These findings are consistent with the hypothesis that interneurons with excitable elements in the distal radiatum, and synapses in the oriens, increase the strength of their projection to the oriens after injury. This inhibition in the oriens, however, was also insensitive to bath application of BCAAs.

Although the Schaffer collaterals provide the primary input to CA1, temporoammonic (TA) pathway fibers from the entorhinal cortex also synapse in CA1. We stimulated the TA pathway to test for changes in TA signaling, and preliminary evidence suggests that inhibition in SR is increased after injury, in a frequency-dependent manner, and restored to normal by BCAAs. We conclude that the BCAA mediated restoration of normal CA1 inhibition after injury occurs primarily via changes in the TA pathway, and not the Schaffer Collaterals.

Title: Lithium reduces bace1 overexpression, beta amyloid accumulation and spatial learning deficits in mice with traumatic brain injury

Authors: *F. YU[1], Y. ZHANG[2], D.-M. CHUANG[1]
[1]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD; [2]Anatomy, Physiol. and Genet., Uniformed Service Univ. of the Hlth. Sci., Bethesda, MD

Abstract: Traumatic brain injury (TBI) leads to both acute injury and long-term neurodegeneration, and is a major risk factor for developing Alzheimer's disease (AD). Beta amyloid (Aβ) peptide deposits in the brain are one of the pathological hallmarks of AD. Aβ levels increase after TBI in animal models and in patients with head trauma, and reducing Aβ levels after TBI has beneficial effects. Lithium is known to be neuroprotective in various models of neurodegenerative diseases and can reduce Aβ generation by modulating glycogen synthase kinase-3 (GSK-3) activity. This study explored whether lithium would reduce Aβ load after TBI and improve learning and memory in a mouse TBI model. Lithium chloride (1.5 mEq/kg, i.p.) was administered 15 minutes after TBI and once daily thereafter for up to three weeks. Western blotting analysis of Aβ and β-APP-cleaving enzyme-1 (BACE1) in the corpus callosum and hippocampus were performed at three days after injury. Immunostaining of Aβ, amyloid precursor protein (APP) and phospho-Tau were also carried out at the same time point. Enzyme-linked immunosorbent assay was further employed to evaluate Aβ42 levels in the corpus callosum and hippocampus after TBI. Results showed that lithium attenuated TBI-induced Aβ load increases, APP accumulation, and BACE1 overexpression in the corpus callosum and hippocampus at three days post-injury. Increased Tau protein phosphorylation in the thalamus

was also attenuated after lithium treatment following TBI at the same time point. Notably, lithium treatment significantly improved spatial learning and memory in the Y-maze test conducted 10 days after TBI, and in the Morris water maze test performed 17 to 20 days post-TBI, in association with increased hippocampal preservation. Thus, post-insult treatment with lithium appears to alleviate TBI-induced Aβ load through blockade of TBI-induced BACE1 overexpression and consequently improve spatial memory. The findings suggest that lithium is a potentially useful agent for managing memory impairments after TBI or other head trauma.

Title: Heat acclimation changes beta catenin fate after traumatic brain injury

Authors: *G. UMSCHWEIF[1], A. ALEXANDROVICH[2], M. HOROWITZ[3], E. SHOHAMI[2]
[1]Inst. of Drug Research,The Hebrew Univ. of Jerusalem, Jerusalem, Israel; [2]Inst. of Drug Res. The Hebrew Univ. of Jerusalem, Jerusalem, Israel; [3]Dept. of Physiology, Fac. of Medicine, The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Traumatic brain injury (TBI) triggers depressive behavior. Depression was earlier shown to be attenuated by inhibitors of glycogen synthase kinase-3 (GSK-3) which is also a potent regulator of cell apoptosis. TBI was shown to increase phosphorylation of GSK-3β and accumulation of its downstream target β -catenin in the hippocampus. Heat acclimation (HA, 30d at 34 ±1°C), a well studied pre-conditioning model, offers benefits against various types of stressors, including TBI (Shein et al 2007) where it reduces depressive behavior. We have observed that in HA mice the pre-TBI levels of brain derived neurotrophic factor (BDNF) are elevated and that Akt phosphorylation levels are increased immediately after TBI (SHein et al., 2008). HA also dramatically reduces apoptosis and caspase 3 activity (Umschwief et al., 2010). In the present study HA mice and their normothermic (NT) controls were subjected to TBI and 24h later we evaluated the changes in GSK3β, a downstream target which is inhibited by pAkt and in turn stabilizes β -catenin, preventing its phosphorylation and degradation. Using Western blot analysis, we found in HA mice elevated levels of pGSK3 β ($p<0.05$ vs NT). However, unexpectedly levels of p- β -catenin were higher in HA mice ($p<0.05$ vs NT), with no further degradation or reduced nucleus accumulation. To reconcile this apparent conflict, we

investigated the fate of β -catenin in NT and HA mice 24h after TBI. We found induction of β -catenin cleavage in NT mice and reduction in its cytosolic levels. On the other hand, co-immunopercipitation showed weaker interaction between β -catenin and membranal N-cadherin in HA mice ($p<0.05$ vs NT) possibly allowing β -catenin to participate in neuro-regeneration process. Elevated tyrosine phosphorylation of β -catenin, is a process downstream to BDNF activity. BDNF, which is elevated in HA mice after TBI, may disrupt β -catenin/N-cadherin interactions in HA mice, and reduce degradation of the cytosolic protein.

Title: 12/15-LOX inhibition reduces neuronal cell death *in vitro* and secondary brain damage after experimental traumatic brain injury

Authors: *N. A. TERPOLILLI[1,2], S. TOBABEN[4], C. BREM[1,2], S. SCHWARZMAIER[3], A. DOLGA[4], B. HOFMANN[5], D. STEINHILBER[5], C. CULMSEE[4], N. PLESNILA[3]
[1]Univ. of Munich, Dept. of Neurosurg., Munich, Germany; [2]Walter Brendel Ctr. for Exptl. Med., [3]Inst. for Stroke and Dementia Res., Univ. of Munich, Munich, Germany; [4]Pharmacol., Univ. of Marburg, Marburg, Germany; [5]Pharmacol., Univ. of Frankfurt, Frankfurt, Germany

Abstract: Excitotoxicity and oxidative stress are important mechanisms contributing to posttraumatic brain damage. Our recent in vitro studies suggested a key role for lipooxygenases (LOX) in intrinsic death pathways involving mitochondrial demise and translocation of apoptosis inducing factor (AIF) to the nucleus. The aim of the present study was to differentiate the effects of 12/15- and 5-LOX inhibition in models of neuronal damage in vitro and in a model of traumatic brain injury (TBI) in vivo.
We used the specific inhibitors PD146176 (12/15-LOX) and YS121 (5-LOX) in different models of excitotoxicity and oxygen glucose deprivation (OGD) in HT-22 cells as well as in primary cortical neurons. In vivo, male C57bl/ 6 mice received different doses of each inhibitor 10 minutes before Controlled Cortical Impact trauma (impact velocity 8m/s, impact depth 1mm). Male 12/15-LOX null mice were used for knock out studies. Lesion volume, brain edema formation, neurological function, and ICP were assessed 24 hours after TBI.

12/15-LOX inhibition protected HT-22 cells and primary cultured neurons from glutamate- and OGD-induced cell death, respectively, while 5-LOX inhibition alone did not have any protective effect. In vivo, 12/15-LOX inhibitor PD146176 (0.4mg/kg) reduced lesion volume 24h after TBI and 12/15 LOX knock out mice showed a tendency towards neuroprotection. In keeping with the in vitro data, 5-LOX inhibition did not influence secondary brain damage after TBI.
In conclusion, 12/15-LOX but not 5-LOX inhibition attenuated neuronal cell death in vitro and posttraumatic brain damage in vivo. Therefore 12/15 LOX may represent a novel therapeutic target for the prevention of secondary brain damage following TBI.

Title: mRNA translation is altered in an *in vitro* model of traumatic brain injury.

Authors: *R. MOTT, D. F. MEANEY
Bioengineering, Univ. of Pennsylvania, PHILADELPHIA, PA

Abstract: Developing effective therapies for traumatic brain injury (TBI)-impaired learning and memory is challenging because the underlying pathology is not fully understood. Neuronal apoptosis and necrosis are well documented mechanisms for dysfunction, but many studies indicate cognitive deficiencies in the absence of neuronal cell death. Changes in receptor expression after TBI suggest the existence of an injury induced ‘pathological plasticity’ that alters the function of the surviving cells. A key calcium-dependent, mechanism implicated in plasticity is dendritic mRNA translation. Previous fluid percussion injury studies by others (Atkins et al., JCBFM, 2006 and Chen et. al, JCBFM, 2007) found CaMKII, CPEB and mTor pathways to be activated in the cortical and hippocampal tissue of injured rats. This in vitro study measures the impact of moderate stretch (55-70%) injury on all three pathways, which are key regulators for both dendritic and global mRNA translation. We find the S6 ribosomal protein, a downstream effector of mTor, and CaMKIIα pathways to be rapidly activated by stretch injury of rat cortical cultures. S6 activation was significant within 30 min of stretch injury (163±17% of

control, n=5, p<.01) and remained elevated for at least 1 hour post injury (166±32% of control, n=5, p<.05). CamKIIα was significantly elevated within 10 min of stretch (122±9.8% of control, n=4, p<.05). The S6 activation was both NMDAR and mTor-dependent, as it could be blocked by pretreatment with APV or rapamycin, but the voltage-gated calcium channel blocker, nimodipine, failed to suppress S6 activation. The impact of stretch injury on mRNA translation was also directly measured using an in vitro imaging assay; changes in translation of dendritically localized mWasabi-tagged proteins were found within minutes of stretch injury. Overall translation rate was measured as the change in fluorescence over time, and increased approximately 5-fold with injury (13.1% vs. 2.6% increase in fluorescence over a ten minute period, n=10 cells, p<.05). Interestingly, the impact of moderate stretch had a negative effect on the activation of CPEB; the phosphorylation of CPEB at Thr171 decreased to 82% of control values within 10 min of injury (n=4, p<.05) under an NMDAR-dependent mechanism. The results of this study suggest that mechanical injury can alter the expression of dendritic proteins via modulation of translational pathways; future studies will aim to determine the impact on individual mRNAs under the regulation of various *cis*-elements including the CPEB regulated CPE.

Abstract: Traumatic brain injury (TBI) is currently untreatable and is the signature affliction of modern deployed forces. Over 300,000 military personnel have received these injuries and the worldwide prevalence is about 0.5% with persistent effects on patients, families, and our healthcare system. We have investigated traumatic brain injury models in vivo and in vitro with the goal of enhancing our understanding of the mechanisms that contribute to TBI induced neurodegeneration. The model systems for these experiments included a closed head, weight drop injury with mice and a rapid, biaxial stretch (mimicking TBI torsional insult) with model neurons in culture. We have previously shown that multiple administrations of tert-butylhydroquinone (tBHQ), an activator of transcription factor Nrf2, result in improved cognitive performance after mild traumatic brain injury (mTBI) and upregulation of HSP70. Here we describe the improvement seen with a single administration of the Nrf2 activator at 30 minutes after injury and that model neurons exposed to mTBI in culture are also protected by tBHQ and that this neuroprotection is blocked by an inhibitor of HSP70. These results may facilitate the identification of therapeutic approaches that could positively affect biological processes occurring during injury-induced loss of neuronal function in the brain and prevent the lasting consequences of these injuries.

Title: The adaptive arm of ER stress - a therapeutic target in traumatic brain injury.

Authors: V. RUBOVITCH, R. BARATZ-GOLDSTEIN, A. SHACHAR, S. EDUT, *C. G. PICK
Tel Aviv Univ., Tel Aviv, Israel

Abstract: We have previously reported that mild traumatic brain injury (mTBI) induced various short and long term cognitive deficits as well as apoptosis in the mice brains. Apoptosis may be caused by prolonged and severe accumulation of misfolded proteins and protein aggregation in the endoplasmic reticulum (ER). ER stress enables the cell to adapt and survive by upregulating

translation of stress response proteins and attenuating global protein synthesis. Insulin like growth factor (IGF-1) is known to be neuroprotective. Hence, the present study was aimed at establishing a novel mechanism for IGF-1 neuroprotection, which involves the adaptive arm of the ER stress. As expected, IGF-1 administration significantly improved memory deficits following mTBI (as assessed by the Y-maze and the Novel Object recognition tests). In addition, mTBI induced a time-dependant elevation of the ER stress sensor protein ATF6 (Activating transcription factor 6). IGF-1 administration had a significant effect on CHOP (C/EBP homologous protein) and phospho-eIF2-alpha (elongation initiation factor alpha) expression following mTBI as was seen by western blot analysis. In addition, immunofluorescent examinations revealed that under IGF-1 administration CHOP was significantly co-localized with phospho-eIF2-alpha in the cortices and hippocampi of mTBI mice. These results confirmed our working hypothesis that IGF-1 exerts at least part of its neuroprotection via the adaptive pathway of the ER stress. A direct activation of eIF2-alpha by the selective phosphatase inhibitor Salubrinal, completely abolished the mTBI-induced damage to the cognitive deficits. Altogether, these results reveal a novel neuroprotective mechanism for IGF-1 and suggest the adaptive eIF2-Alpha pathway as a possible target for pharmacological therapy.

Title: Myelin sheath decompaction, axon swelling and functional loss during chronic secondary degeneration in rat optic nerve

Authors: *S. A. DUNLOP[1], S. C. PAYNE[2], C. A. BARTLETT[2], A. R. HARVEY[3], M. FITZGERALD[2]
[1]The Univ. of Western Australia, Nedlands, WA, Australia; [2]Animal Biol., [3]Anatomy, Physiol. and Human Biol., The Univ. of Western Australia, Nedlands, Australia

Abstract: Purpose: To examine disruptions in optic nerve (ON), axons, myelin and visual function during the chronic phase of secondary degeneration, up to 6 months after partial injury.
Methods: Dorsal ON axons were transected, leaving ventral ON as the area vulnerable to secondary degeneration. At 3 and 6 months following partial ON transection, toluidine blue stained sections were used to assess dimensions of the ON injury site. Transmission electron microscopy (TEM) images of ventral ON were used to quantify numbers, diameter, area and myelin thickness of axons with normal and decompacted myelin. Immunohistochemistry (MBP, β-III tubulin) and fluoromyelin staining were used to semi-quantitatively assess myelin protein, lipids in ventral ON, and RGCs in mid-ventral retina. Visuomotor function was assessed using the optokinetic nystagmus test.
Results: Ventral ON and axons, vulnerable to secondary degeneration, as well as visual function remained disrupted 6 months following partial ON transection. Although ventral ON swelling observed at 3 months ($p \leq 0.05$) was no longer seen at 6 months, at the ultra-structural level, myelinated axons remained swollen ($p \geq 0.05$) and myelin thickness had increased ($p \leq 0.05$) due to loosening of lamellae. Axons with decompacted myelin persisted and were distinguished as having large axonal calibres. Progressive loss of myelin lipids was also seen at 6 months. Despite no further loss of ventral axons between 3 and 6 months ($p \geq 0.05$), visuomotor function had progressively declined by 6 months following partial ON transection ($p \leq 0.05$).
Conclusion: Decompaction of myelin and the swelling of myelinated axons are persistent features of secondary degeneration and likely contribute to progressive loss of visual function.

Title: Similar enhancement in dentate network excitability despite marked differences in early cellular injury following fast- and standard-rate concussive brain trauma.

Authors: *E. J. NEUBERGER[1], R. A. WAHAB[2], A. JAYAKUMAR[1], B. J. PFISTER[2], V. SANTHAKUMAR[1]
[1]Univ. of Med. & Dent. New Jersey, Newark, NJ; [2]New Jersey Inst. of Technol., Newark, NJ

Abstract: The primary cause of concussive brain injury can include a wide spectrum of insults ranging from explosions in combat to falls by the elderly. Accordingly, the kinematics of the trauma can vary in key features including the rate and magnitude of the insult. In the fluid percussion injury (FPI) model, the effect of peak injury pressure on neurological outcome has been well examined. However, it is unknown whether differences in the rate of rise of the injury waveform can lead to distinct cellular and physiological changes in the hippocampus. We created a novel programmable voice-coil driven FPI device capable of producing pressure waves with different rise times to address this question.
Young adult male rats (25 day) were subject to lateral FPI at a constant peak pressure (2 atm) with a rise time of either 3 ms (fast-rate) or 10 ms (standard-rate of conventional FPI). Histological and physiological studies were conducted in hippocampal slices obtained 4-6 hours and 7-10 days after FPI and in sham-injured controls. Fast-rate FPI resulted in immediate behavioral seizures and fatalities in significantly fewer rats than after standard-rate FPI. Numerous hilar neuronal profiles were labeled by the Gallyas stain indicating extensive mechanical injury after standard-rate FPI. In contrast, only a few hilar neurons were labeled after fast-rate FPI. Similarly, FluroJade staining immediately after fast-rate FPI revealed fewer degenerating neurons in the dentate hilus and CA1 compared to standard-rate FPI. One week after injury, hippocampal slices from rats subject to both fast- and standard-rate FPI showed a significant enhancement of the perforant path-evoked granule cell field responses compared to sham controls. Notably, despite the early differences in cellular injury, the afferent-evoked dentate population spike amplitude measured one week after fast- and standard-rate FPI was not different.
These data demonstrate the rate of rise to peak pressure of the injury waveform plays a crucial role in determining the extent and subtype specificity of regional cell loss. Our data indicate that reduced cellular damage and improved immediate neurological outcome, may obscure the severity of neurophysiological changes after fast-rate injury. Our findings suggest that strategies used to assess and manage patients with relatively slower civilian TBI may not directly apply while evaluating patients with fast-rate, blast-related TBI.

Center, Veterans Affairs Pittsburgh Hlth. Care Syst., Pittsburgh, PA

Abstract: Traumatic brain injury (TBI) is a leading cause of motor and cognitive deficits in young adults without an effective therapeutic agent to date. Treatment with histone deacetylase inhibitors (HDI) limiting deacetylase activities have shown to preserve motor and cognitive function after TBI. In this study, we characterized the protective capacity and mechanism of a new inhibitor of class I and II histone deacetylase, *Scriptaid*, on injury induced by controlled cortical impact (CCI).

Scriptaid when introduced at doses between 1.5 to 5.5 mg/kg, 30 minutes post-injury, elicited a dose-dependent decrease in lesion size as well as a concomitant attenuation in motor and cognitive deficits as determined by wire-hanging, cylinder, foot fault and Morris water maze tests. Furthermore, protection against neuronal degenration and behavioral deficits from *Scriptaid* was observed 35 days post-injury and when its administration was delayed to 12 hr post-injury demonstrating its long term efficacy with relative wide therapeutic window for this HDI. The improvement in neurobehavioral functions conferred by *Scriptaid* was also mirrored by a corresponding increase in surviving neurons within the CA3 region of the hippocampus. To ascertain the protective mechanism of *Scriptaid*, we looked for the activation of various protective pathways. Immunohistochemical staining and Western blot analysis revealed a decrease in phopho-AKT (pAKT) and phosphorylated phosphatase and tensin homolog deleted on chromosome 10 (pPTEN) after TBI in the cortex and CA3 region with no detectable change in the total AKT and PTEN protein levels. Mechanistically, the decrease in pPTEN stabilizes PTEN which in turn prevents the phosphorylation of AKT. However, this decrease in pAKT and

pPTEN were reversed after treatment with *Scriptaid*. As expected, further addition of LY294002 (an inhibitor of the AKT pathway) abolished the protection conferred by *Scriptaid* suggesting its main protection was derived from the activation of the AKT pathway. In summary, our study has shown that *Scriptaid* is an effective pharmacological agent that modulates PTEN and the AKT pathway to protect against TBI injury.

Title: Cognitive amelioration of mild traumatic brain injury by exendin-4 and PFTα

Authors: *L. RACHMANY RABER[1], D. TWEEDIE[2], V. RUBOVITCH[1], Q.-S. YU[2], N. H. GREIG[2], C. G. PICK[1]
[1]Dep.Of Anat. and Anthropology, Sackler Sch. of Medicine, Tel-Aviv Univ., Tel-Aviv, Israel; [2]Drug Design & Develop. Section, Intramural Res. Program, Natl. Inst. on Aging, Natl. Inst. of Hlth., Baltimore, MD

Abstract: Traumatic Brain Injury (TBI) annually impacts 1.7 million Americans, causing considerable suffering, with no effective current treatment. Mild TBI (mTBI) accounts for 80% of TBI events and can have enduring consequences. Prior studies have shown that mTBI may lead to long-term cognitive, emotional, and behavioral deficits. Additionally, mTBI-triggered changes in the gene expression, biochemical cascades and apoptotic neuronal degeneration, particularly in the cortex, hippocampus and forebrain, provides a potential gateway to late-term disorders, such as Alzheimer's disease (AD) and Parkinson's disease (PD). Two different therapeutic approaches were assessed to halt mTBI neuronal apoptosis and trigger reparative processes: exendin-4 (Ex-4), a long-acting glucagon-like peptide-1 (GLP-1) receptor agonist approved for type 2 diabetes treatment, and the experimental anti-apoptotic tetrahydrobenzothiazole analogue, pifithrin-α (PFTα). Both agents readily enter the brain, and whereas Ex-4 has demonstrated neurotrophic/neuroprotective actions in cellular and animal

models of AD and PD, and is in current clinical assessment for these disorders, PFTα, which inhibits p53-mediated translocation and lowers transcription, has been reported to prevent neuronal loss in cellular and animal models of stroke, PD and AD. mTBI was induced by a non-invasive closed-head weight drop device and 30 g weight, and behavioral and cognitive exams were conducted either 7 or 30 days post trauma. Mice subjected to mTBI demonstrated a deficit in visual memory compared to sham control mice at both assessment times. Administration of either Ex-4 or PFTα post-mTBI proved well tolerated, fully ameliorated this impairment, and may provide a clinically translatable treatment strategy.

Title: Inhibition of p75 pathway improves outcome following traumatic brain injury

Authors: *J. ALDER, W. FUJIOKA, A. GIARRATANA, B. PATEL, T. CHAKRABORTY, A. PARIKH, H. GIRN, S. THAKKER-VARIA
Dept Neurosci Cell Biol, UMDNJ - Robert Wood Johnson Med. Sch., PISCATAWAY, NJ

Abstract: Following traumatic brain injury (TBI), changes in metabolic, cytotoxic and apoptotic processes lead to pathophysiological alterations in the cortex and hippocampus. Along with mature neurotrophins' well-established role of regulation in neural development and adult synaptic plasticity in the hippocampus and cortex, the precursor form of neurotrophins, the pro-neurotrophins, are known to control neuronal apoptosis and long-term depression. Studies indicate that Brain-Derived Neurotrophic Factor (BDNF) is transiently elevated after TBI. However, the increase in expression of the trophic factor in the brain following TBI is not sufficient to support complete regeneration, suggesting that the role of BDNF in pathological conditions is not entirely understood. As it is not yet known whether the mature BDNF and its receptor TrkB which supports cell survival or the proBDNF isoform and its receptor p75 which causes cell death are upregulated following TBI, the consequences of the increased BDNF levels for recovery processes remain to be elucidated. We hypothesize that the toxic proBDNF/p75 pathway is the predominant one upregulated after injury, suggesting that it may be partly

responsible for the deleterious consequences of brain injury. We are using lateral fluid percussion injury (LFP) to model moderate TBI and examine whether there is increased signaling through p75 receptor either through upregulated proBDNF and/or p75 expression. Our results indicate that p75 is upregulated and trkB is downregulated after LFP in the hippocampus and cortex. To reveal the identity of the cells expressing the specific BDNF receptors, immunohistochemistry was performed to co-localize trkB or p75 to specific cell types. p75 receptors were found to be associated predominantly with astrocytes after TBI and trkB with neurons. To determine whether lack of p75 signaling confers protection against neuronal damage following TBI, we have used activated caspase-3 and Flouro-Jade C to quantitate neural cells undergoing cell death and neurodegeneration in wild type and p75 null mice. Our ultimate goal is to study whether the impairment of cognitive and motor function following TBI is reduced in the absence of p75 signaling. Behavioral experiments demonstrate that there is improved response in the vestibulomotor rotarod test and in the spatial learning Morris Water Maze test in mice with reduced p75 following LFP when compared to wild type mice indicating that p75 signaling pathway may contribute to the damage following TBI. We are currently using small molecules to inhibit the p75 pathway and activate the TrkB pathway to measure histological and behavioral outcomes following injury.

Title: *In vivo* and *in vitro* neuronal and astro-vasculature correlates in the somatosensory cortex after traumatic brain injury

Authors: *M. K. JAISWAL[1,2], F. W. LISCHKA[1,2], Z. GALDZICKI[1,2]
[1]Ctr. For Neurosci. and Regenerative Medicine, USUHS, Bethesda, MD; [2]Dept. of Anatomy, Physiol. and Genetics, USUHS, Bethesda, MD

Abstract: Clinical evidence indicates that TBI is linked to the development of dementia and cognitive dysfunction, suggesting that TBI may damage nearby neurons, astrocytes and associated neuro-astro-vasculature coupling. In addition previous in vitro work has shown that a balance between excitation/inhibition networks has been disrupted in major neurological disorders like epilepsy, schizophrenia and autism. We hypothesize that TBI impacts the balance of excitatory/inhibitory sensory circuits with vascular defects exacerbating neuronal recovery. In this study we focused on the assessment of network activity by 2-photon in vivo imaging to monitor activity of excitatory/inhibitory neurons in GAD67-GFP knock-in mice. In order to control for the impact of vascular injury on neuronal activity, we monitor vascular changes caused by damage to the integrity of the BBB with dye specific for blood vessels/arteries with simultaneous recordings of calcium transients in neurons and astrocytes by 2-photon imaging in cortical tissue followed by TBI.
2-photon calcium imaging revealed a decrease in neuronal activity (higher number of hypoactive neurons) in excitatory/inhibitory layer 2/3 cortical neurons within 300-500µm from injury epicenter in TBI mice. At the same time some of the neurons displayed an unexpected increase in their calcium transients (hyperactivity) in the frequency of spontaneous Ca2+ transients in TBI neurons in comparison to sham littermates. Electrophysiological characterization of the neurons in the vicinity of the injury in TBI mice shows altered spontaneous activity in comparison to the sham control. In excitatory neurons of TBI mice we have observed a shift of cumulative probability towards the higher amplitude of spontaneous EPSCs in comparison to sham control, whereas opposite trend have been seen in fast-spiking inhibitory neurons. Overall, our results suggest desynchronization of neocortical activity following TBI with an impaired inhibition underlying hyperactivity/hypoactivity of excitatory neurons possibly due to disruption of feedback inhibition. In order to preserve intact circuitries and maintaining blood supplies to cortex in vivo approach has been initiated in combination with electrophysiology in a mouse model of TBI. The 2-photon recordings will be done in parallel with vascular assessment to monitor multi-network calcium imaging to identify alterations in network dynamics produced by TBI in correlations to vascular damage. In summary, our results suggest that dysfunctional cortical circuit likely contributes to the pathophysiology of TBI and the vascular damage plays an important role in pathophysiology of TBI.

Title: Mild Traumatic Brain Injury affects excitatory synaptic transmission in the medial prefrontal cortex, an area distant from injury site

Authors: *C. SMITH[1,2], C. P. PALMER[2], G. XIONG[1], J. A. ELKIND[1], O. VENEGAS[2], B. PUTNAM[2], A. S. COHEN[1,2]

Abstract: Traumatic Brain Injury (TBI) affects more than 1.5 million people in the United States each year and even mild TBI can lead to a vast array of long-lasting neurological impairments (Rutland-Brown et al., 2006). Despite its prevalence, currently no therapy exists to mitigate or treat the underlying causes of cognitive impairments suffered by TBI patients. TBI predominantly causes damage to the frontal and temporal lobes of the cerebral cortex; this damage causes significant neuropsychological sequelae, including persistent memory deficits that disrupt the lives of TBI survivors (Stuss, 2011). The medial prefrontal cortex (mPFC) is critically involved in higher cognitive functions, including memory, that are disturbed by mild traumatic brain injury (mTBI). In order to model mTBI in mice we employed lateral fluid percussion injury (LFPI). LFPI is a commonly used rodent model of brain injury that reproduces many key features of human TBI including neuronal cell loss, gliosis, ionic perturbation and memory deficits (Dixon et al., 1987, McIntosh, 1987, 1989, Smith et al., 1991). Following an LFPI designed to mimic an mTBI we investigated alterations to synaptic transmission in the prelimbic cortex, the functional homolog of human mPFC. After mTBI, amplitude of presynaptic fiber volleys from layer 2/3 stimulation as well amplitude of field excitatory postsynaptic potentials recorded in layer 5 were reduced in brain-injured mice. When fiber volley size was normalized, fEPSPs were significantly reduced in slices derived from brain-injured mice. Furthermore, whole-cell patch clamp recordings revealed that the frequency and amplitude of spontaneous and miniature excitatory postsynaptic currents (sEPSCs, mEPSCs) were increased in layer 2/3 neurons in brain slices derived from brain-injured animals. Investigations regarding excitatory currents in layer 5 neurons, as well as anatomical analyses of both layer 2/3 and layer 5 neurons are ongoing. These results demonstrate that excitatory synaptic transmission in the mPFC is functionally altered by mTBI and may contribute to observed behavioral and cognitive deficits.

Title: Structural and molecular adaptions induced by traumatic brain injury (TBI) in mice

Authors: *D. P. CROCKETT, K. P. BALDEV, K. K. PATEL, R. R. BHAVSAR, V. L. DIBONA, M. R. RASIN, H. ZHANG

Abstract: At least 1.4 million people each year suffer from traumatic brain injury (TBI) with the cost to the economy estimated to be in excess of $60 billion according to the CDC. Even mild TBI can cause a wide range of pathologies including diffuse axonal injury, secondary cell death (including oligodendrocytes) and inflammation, which may be progressive, affecting the deep white matter and disrupt local circuitry distant from the focal injury site. These consequences can lead to continued loss of function. We have been studying the biology of TBI in mice subjected to either lateral fluid percussion injury (LFPI) or controlled cortical impact injury (CCI). We have found plastic changes of the homologous region of the contralesional neocortex 7 and 30 days post-TBI. In particular, we observed altered dendritic structure revealed by decreased SMI32 (hypo-phosphorylated neurofilament) immunoreactivity in projection neurons of layers 2 and 3. Our data suggest that cell death does not seem to account for these observations in the contralesional cortex. However, evidence of apoptosis was observed in the ipsilateral hemisphere. In order to elucidate the underlying mechanisms responsible of TBI induced changes in projection cell polarity, we stained for importin 13 (IPO13) and eukaryotic initiation factor 4e (eIF4e), which were reported to be disrupted in the contralesional neocortices after a hemisection spinal cord injury (SCI) (Thompson et al., 2010). Surprisingly, immunostaining levels for IPO13 and eIF4e were unchanged in the contralesional cortex at 7 days post TBI. These data suggest that TBI induces acute adaptive changes in contralesional neocortices that are different than those induced by hemisection SCI. Indeed, we found an increased expression of histone deacetylase 1 (HDAC1) and β-amyloid precursor protein within the corpus callosum that are indicative of axonal pathology and likely disruption of inter-hemispheric communication following TBI. We plan to further explore the mechanisms that underlie the reorganization of

cortical microcircuitry following TBI using transgenic mice expressing fluorescent markers (e.g., Thy1-YFP expressing mice) and 2-photon microscopy. This will allow us to further define injury-induced alterations (both structural and molecular) in cortical microcircuitry.

Abstract: Astrocytes are thought to play a critical role in the survival of other cellular cortical tissue elements, and their response to a significantly altered cellular environment is often reflected in morphologic changes. Our study is the first to characterize time-based astrocytic changes after human TBI and to compare these changes with human control tissue removed in the course of surgical treatment of temporal lobe epilepsy.
Cerebral cortex samples were surgically resected from 17 patients with a clinical diagnosis of blunt TBI and from one epilepsy patient with partial onset seizures. All procedures were approved by our Institutional Review Boards.
The astrocytes of the control cerebral tissue were characterized by round to oval nuclei with a thin rim of condensed chromatin at the nuclear membrane. Peripheralized nucleoli rarely were present. Perinuclear cytoplasm was scanty and often not visible. The astrocytic perivascular foot processes surrounding capillaries were thin profiles containing few cytoplasmic organelles.
At 6 hours post-injury, there was swelling of perivascular astrocytic end-feet as well as some astrocytic foot processes surrounding neuronal cell bodies Perikarya of those neurons showed a

reciprocal decrease in the cross sectional area of their cytoplasm.
At 38 hours post-injury, there was increased expansion of astrocytic cytoplasm in perikarya and proximal processes, the astrocytic nuclei were larger and paler as compared with those of TBI cerebral tissue resected at 6 hours post-injury. The perivascular end-feet were remarkably swollen and many of them were degenerated. The swollen astrocytic end-feet compressed the microvessels and appeared to induced microvascular obstruction as evidenced by red blood cell stasis. There was an increased number of advanced swollen and degenerated astrocytic end-feet surrounding neuronal cell bodies. Some of these neurons showed advanced levels of degeneration. Paired astrocytic nuclei occasionally were seen.
By 7 days post-injury, the majority of swollen astrocyte cell bodies and their foot processes had become necrotic; and microvascular compression as evidenced by stasis had almost disappeared. Astrocyte proliferation and hypertrophic astrocytes with multiple nuclei (2 and more) were frequently seen.
This study shows that over the course of the first seven days after human TBI the astrocytic population undergoes a variety of both degenerative and proliferative changes while in contact with the microvasculature and with neurons.

Title: The effects of blueberry supplementation in middle aged mice consuming a high fat diet.

Authors: *A. N. CAREY, B. SHUKITT-HALE
Neurosci. Lab., USDA-ARS Human Nutr. Res. Ctr., BOSTON, MA

Abstract: Consuming a high fat diet may result in behavioral deficits that are similar to those observed in aging animals, possibly because of increased brain inflammation and oxidative stress. Our lab has demonstrated that diets supplemented with polyphenolic-rich berries, such as blueberries, can allay behavioral deficits associated with aging. Thus, it stands to reason that supplementation of a high fat diet with blueberry may offer protection against these putative high fat diet-related declines. Nine month old C57Bl/6 mice were maintained on one of four diets for

a five month period: low fat (Harlan, TD.08806, 10% calories from fat), low fat + 4% blueberry (freeze-dried extract, provided by the U.S. Highbush Blueberry Council), high fat (TD.06414, lard-based, 60% calories from fat), and high fat + 4% blueberry. Mice were tested with the novel object recognition memory task after 2, 3, and 4 months on the diets. Mice were also tested in the Morris water maze for spatial memory after 5 months on the diets. Studies are ongoing, but preliminary data suggest that recognition memory performance was impaired by high fat diet and blueberry-supplementation prevented some of the recognition memory deficits. The goal of the study is to begin to determine if making small changes to a poor diet, like incorporating more nutrient dense foods, may allay or prevent cognitive dysfunction associated with consumption of a high fat diet.

Title: Serum metabolites from walnut-fed aged rats attenuate stress-induced neurotoxicity in brain cells *in vitro*

Authors: S. M. POULOSE, D. R. FISHER, *D. F. BIELINSKI, B. SHUKITT-HALE
Neurosci. & Aging Lab., USDA Human Nutr. Res. Ctr, Tufts Univ., BOSTON, MA

Abstract: The shift in equilibrium towards excess reactive oxygen or nitrogen species production from innate antioxidant defense in brain is a critical factor in the declining neural functions and cognitive deficits accompanying age. In aging, there are noticeable alterations in the membrane microenvironment, with increased oxidized proteins and lipids, altered calcium buffering, accumulation of damaged organelles and protein structures, weak neurotransmitter release, and dystrophy and death of neurons. Previous studies from our laboratory have reported that walnuts, rich in polyphenols, antioxidants, and omega fatty acids such as alpha linoleic acid (ALA) and linolenic (LA), improve the age-associated declines in cognitive and neural deficits in rats. Possible mechanisms of action of these effects include enhancing protective signaling, altering membrane microstructures, decreasing inflammation, and preventing accumulation of

polyubiquitinated protein aggregates in critical regions of the brain. In the current study, we investigated whether the serum collected from aged animals fed with walnut diets (0, 6% and 9%) would enhance protection on stressed BV2 microglial and HT22 hippocampal neurons, in vitro. In the growth medium, fetal bovine serum (FBS) was substituted with the serum collected from 22 month old rats fed with either walnut or control diets for 12 weeks. Walnut diet serum (6 and 9%) significantly attenuated dopamine-(DA-)induced neurotoxicity, as measured by recovery from calcium influx in potassium chloride-(KCl-)induced depolarized hippocampal neurons. Additionally, walnut diet serum (6 and 9%) significantly attenuated lipopolysaccharide-(LPS-)induced nitrite release in the microglial cells. Neither control serum nor FBS alone (negative control) elicited similar rescuing effects on either type of brain cell. While identification of the individual metabolites, as well as the measurement of oxidant/antioxidant enzymes in these sera are being done, preliminary results strongly suggest protection or enhancement of membrane-associated functions in brain cells by walnut serum metabolites.

Title: Human cognition and mobility in aging: A model for berry fruit interventions

Authors: *M. G. MILLER[1], B. SHUKITT-HALE[2]
[1]Psychology, Tufts Univ., Medford, MA; [2]Neurosci. and Aging, USDA-HNRCA, Boston, MA

Abstract: Changes in motor function in aging, in both animals and humans, include decrements in balance, strength, and coordination, even in the absence of specific movement disorders such as Parkinson's disease. In humans, these alterations can increase fall risk, often leading to injury and premature nursing home admissions. Parallel to alterations in motor function, changes in cognitive function in aging include decrements in learning, memory, and spatial cognition, even in the absence of specific neurodegenerative diseases such as Alzheimer's disease. In humans, these alterations can lead to decreased productivity, independence, and quality of life. In the present study, men and women between the ages of 21 and 75 years were recruited to investigate parallel declines in cognition and mobility. Balance and gait were measured using a treadmill

instrumented with an array of high-density pressure sensors. Balance was assessed during both eyes-open and -closed conditions. Gait was assessed at both 1.5 mph and preferred walking speeds. Spatial learning and working memory were measured using a virtual version of the Morris water maze (vMWM) task and executive function was measured using the trail-making test (TMT). Results show that increased age was associated with increased postural sway during quiet standing and declines in preferred walking speed. Increased age was also associated with declines in spatial navigation ability, characterized by increasing acquisition latencies and impaired probe trial performance in the vMWM. Similarly, increased age was associated with declines in psychomotor speed and executive function as measured by the TMT. Dietary interventions with berry fruit are able to rescue cognitive and motor performance in animal models; the test battery employed in the present study may therefore present a useful model for assessing the effect of dietary interventions in older adults.

Title: Acai fruit improves motor and cognitive function in aged rats

Authors: *B. SHUKITT-HALE, A. N. CAREY, M. G. MILLER, S. M. POULOSE
USDA, ARS, Human Nutrit Res. Ctr. On Aging, BOSTON, MA

Abstract: Aged rats show impaired performance on motor and cognitive tasks that require the use of spatial learning and memory. In previous studies, we have shown the beneficial effects of various berry fruits (blueberries, strawberries, and blackberries) in reversing age-related deficits in behavioral and neuronal function when fed to rats from 19-21 months of age. These effects may be the result of increasing antioxidant and/or anti-inflammatory levels, or by direct effects on signaling and autophagy, in the brain. Acai is a black-purple fruit (genus *Euterpe*) cultivated in the Amazon delta and in Brazil (*Euterpe oleracea* Mart. -EO), as well as southern Central America and Columbia (*Euterpe precatoria* Mart. - EP), and it is known to be rich in polyphenolics that may affect cell-to-cell signaling, receptor sensitivity, inflammatory enzyme

activity or gene regulation. Thus, the present studies were carried out to determine if EO or EP, fed in the rat diet at 2% for 8 weeks, would be efficacious in reversing the deleterious effects of aging on motor and cognitive behavior in 19 mo Fischer 344 rats. Results for the motor testing showed that the EO diet improved performance on wire suspension, while the EP rats turned more on the planks, leading to improved balance performance. Additionally, the EO diet improved reference and working memory in the Morris water maze compared to control, but not the EP, diet. We are currently assessing whether alterations in signaling and autophagy may be involved in the mechanisms of action through which the acai polyphenols could be producing their effects.

Title: Investigating the neuroprotective effects of American skullcap (Scutellaria lateriflora)

Authors: M. LOHANI[1], M. AHUJA[2], D. SHANNON[3], A. RIMANDO[4], D. SCHWARTZ[1], B. KEMPPAINEN[1], *M. DHANASEKARAN[2]
[1]Col. of Vet. Medicine, Auburn Univ., Auburn, AL; [2]Harrison Sch. of Pharmacy, Auburn Univ., Auburn, AL; [3]Col. of Agr., Auburn, AL; [4]USDA, Oxford, MS

Abstract: Introduction: Oxidative stress plays an important role in the pathogenesis of neuronal diseases, resulting in cellular damage and possibly cell death. Bioactive compounds (e.g., phytochemicals) present in medicinal plants neutralize or scavenge unstable/toxic free radicals thus preventing them from attacking vital components of cells. American skullcap, a native plant of North America has been used by Americans and Europeans as a nerve tonic, sedative and anticonvulsant for more than 200 years. However, the neuroprotective effects of American skullcap are not fully understood. Therefore, the objective of this study is to investigate the antioxidant effects of American skullcap.
Methods: The antioxidant potential of aqueous or alcoholic extracts of American skullcap was determined in rat brain tissue. In-vitro and quantitative PCR assays were used to determine the antioxidant effects of American skullcap.
Results and Conclusion: Both ethanolic and aqueous extracts of American skullcap expressed

antioxidant activities. The ethanolic and aqueous extracts dose-dependently scavenged the 1,1-diphenyl-2-picrylhydrazyl (DPPH) free radicals. Only the ethanolic extract scavenged the hydroxyl radicals (3-fold greater activity compared to positive control, ascorbic acid) and reduced the lipid peroxidation (16% decrease compared to negative control) in the mouse brain homogenate. Protein (5.9 ug/mg vs. 0.00021 ug/mg) and glutathione content (0.275 ug/mg vs. 0.191 ug/mg) were greater in ethanolic than aqueous extracts of American skullcap when determined using colorimetric and fluorometric methods, respectively. However, incubation of the alcoholic extract with the hippocampal cells did not affect the gene expression of catalase and superoxide dismutase. In conclusion, due to the presence of glutathione and other polyphenols, American skullcap exhibits antioxidant activities and prevents neuronal damage. Hence, American skullcap has good potential as a therapeutic agent in the future for various neuronal disorders.

Title: Berry extracts protect cortical cells from mechanically induced trauma

Authors: L. CHIBRIKOVA, E. KELLY, E. SHEA, M. Z. HOSSAIN, *J. T. WEBER
Sch. of Pharm., Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Oxidative stress is believed to contribute to aging, as well as cell damage and death in neuropathologies such as stroke and traumatic brain injury. Foods containing particularly high amounts of antioxidants (e.g. polyphenols in berries) may offer a potential means of protection against traumatic insults. We have previously found that oxyresveratrol, a potent antioxidant derived from mulberry wood, protects cortical neurons from traumatic injury in vitro. Chemical analysis of extracts from bilberries and lingonberries demonstrates that these berries contain several anthocyanins and flavonols known to have antioxidant capacity. Therefore, we tested the potential of these extracts to provide protection against traumatic injury. Primary cortical cell

cultures were produced from neonatal rats (P1-3). An in vitro model of traumatic injury was used to produce mild linear mechanical strain. Cells were analyzed using immunohistochemical techniques, including DAPI, which labels the nuclei of all cells, as well as antibodies for MAP-2 and NeuN, which label only neurons. Lactate was measured in culture media using a multi-assay biochemical analyzer. Mild injury caused a significant loss of neurons when measured 24 hr post-injury, but there was no significant loss of glia. Bilberry extracts were added to cultures 15 min before injury, which decreased the extent of neuronal loss at 24 hr. A high level of lactate was observed in media 15 min after injury, indicating that cells were unhealthy, and the addition of bilberry extracts significantly inhibited the trauma-induced rise in lactate. Addition of lingonberry extracts 15 min pre-injury significantly protected against cell loss at 24 hr. Trauma also appeared to increase the expression of microtubule-associated protein light chain 3 (LC3), a marker of autophagy, and lingonberry treatment decreased LC3 expression after trauma. Although further experimentation is necessary, these results suggest that compounds derived from natural products may offer protection from insults such as mild traumatic brain injury, which likely involves oxidative stress.

Title: Resveratrol promotes neuron survival in primary postnatal cultures

Authors: *M. AGRAWAL[1], S. DORE[1,2]
[1]Dept. of Anesthesiol., [2]Neurology, Psychiatry, Neurosci., CTRND, Univ. of Florida Col. of Med., Gainesville, FL

Abstract: Primary dissociated neuronal cultures remain an important mainstay of neuroscience research. Various media have been optimized for neuronal survival and development in cell culture. Serum free media necessitate a number of supplements to support enriched neuronal cultures. The standardized B27 supplement with neurobasal medium has been used to facilitate neuronal growth and attenuates glial proliferation. Our goal is to identify supplements that can improve neuron survival of postnatal neuronal cultures. We have documented that resveratrol

(3,4’5-trihydroxystilbene), a natural polyphenol and a bioactive component of red wine, have numerous neuropropective properties. We have postulated that this stilbene would not likely act as a direct antioxidant but act as a bioactive agent capable (even in small amount) to induce an intracellular cytoprotective cascade. Postnatal cultures of cortical neurons were derived from 0- to 1-day-old C57BL/6 mice. Neurons were plated at a density of 5 million cells per well in three different media: neurobasal medium without any supplement (NBM), neurobasal medium without any supplement but containing resveratrol 10μM (NBM+R10μM), and neurobasal medium with B27 supplement (NBM+B27). Cells were maintained in growth medium at 37°C in a 95% air/5% CO_2 humidified atmosphere. In order to assess neuronal morphology, pictures were acquired from inverted microscope at 24, 48 and 72h after plating for resveratrol induced neuronal attachment. Significant increase in live cells (52.9+/-5.5% and 53.6+/-4.5%, $p<0.0001$) was recorded in cultures incubated in NBM+R10μM and NBM+B27 respectively, when compare to NBM by calcein-AM assay and increase in viability (140.8+/-8.5% and 134.3+/-6.5%) by MTT assay. Significant decrease in dead cells (73.9+/-6.3% and 74.7+/-5.3%, $p<0.0001$) was recorded in cultures incubated in NBM+R10μM and NBM+B27 respectively, when compare to NBM by EthD-1 assay and decrease in cytotoxicity (17.9+/-2.5% and 19.4+/-2.8) by LDH assay. Results indicated that growth of primary neurons in resveratrol containing medium was as good as comparable to B27 supplement medium revealing that resveratrol itself is sufficient to enhance neuronal attachment and survival during plating and can potentially be a substitute of growth supplement. Efforts are currently being conducted to characterize the mechanism by which resveratrol can limit cell death and increase neuron survival.

Title: PC12 cells are influenced differently by resveratrol depending on their differentiation

Authors: N. HAYAKAWA[1,2], M. SHIOZAKI[3], M. SHIBATA[4], M. KOIKE[5], Y. UCHIYAMA[5], *T. GOTOW[1]
[1]Lab. of Cell Biol., Koshien University, Col. of Nutr., Takarazuka/Hyogo, Japan; [2]Lab. Mol. Pathol., Osaka Univ. Grad. Sch. Med. Hlth. Sci., Suita, Japan; [3]Dept. Cardiovasc. Surg., Osaka Univ. Grad. Sch. Med., Suita, Japan; [4]Div. Gross Anat. Morphogen., Niigata Univ. Grad. Sch. Med. Dent. Sci., Niigata, Japan; [5]Dept. Cell Biol. Neurosci., Juntendo Univ. Grad. Sch. Med., Tokyo, Japan

Abstract: Resveratrol (RSV), a polyphenol found in grape skin and red wine, has attracted great interest due to its diverse health benefits including neuroprotection and antitumor effect. We analyzed how RSV (1, 10 and 100 μM) influenced undifferentiated (naive) and differentiated PC12 cells, because naive PC12 cells were tumorigenic in nature while differentiated ones, pretreated with NGF (50ng/ml for 24hr), were neuronal, both of which were from the same cell line. Morphological, immunocytochemical and biochemical methods were used to clarify especially the difference of mitochondrial and autophagy functions between two types of cells. Compared to RSV-untreated (control) PC12 cells, the cells treated with RSV for 48hr showed the following results: Mitochondrial number and ATP synthase β subunit expression were almost unchanged until 10 μM RSV and significantly reduced at 100 μM RSV in naive cells, but significantly increased and unaltered, respectively, in any doses of RSV in differentiated cells. Autophagosomes, sometimes with autolysosomes, were, as in the control, visible in any RSV doses but more conspicuous in 10 and 100 μM RSV-treated differentiated cells. LC3-II, a maker for autophagy, was gradually reduced in expression in a RSV dose-dependent manner in naive cells, but constantly expressed until 10 μM RSV and significantly higher at 100 μM RSV in differentiated cells. At 100 μM RSV, most naive cells were dead without any sign for neurite outgrowth, indicating that they were killed by high dose of RSV. In NGF-treated cells, some cells were also dying or dead at 100 μM RSV, suggesting that the cells, which are not yet differentiated without neurites, are killed by high dose of RSV, but differentiated cells are protected even by such RSV dose, possibly due to the activation of mitochondria and autophagy. Phosphorylated form of AMP-activated kinase (AMPK), a bioenergetic sensor, was more expressed in both cells in a dose-dependent manner, suggesting that RSV-activated AMPK is harmful for naive cells but beneficial to differentiated ones. SIRT1 was more reduced in expression in naive cells especially at 100 μM RSV, but SIRT3 was enhanced slightly in differentiated cells at 100 μM RSV. However, expression ratio of Bcl-xL/Bax at 100 μM RSV was more enhanced in naive cells than in differentiated ones, meaning that naive cells may be

killed by RSV through a cascade different from the Bax-related apoptosis. In conclusion, RSV kills PC12 cells when they are undifferentiated or tumorigenic, but protects them when differentiated or neuronal with extensive neurites, possibly through a mechanism related with mitochondria and autophagy including AMPK activation pathway.

Title: Mangiferin, a natural xanthone ameliorates 6-hydroxydopamine-induced neurocytotoxicity and oxidative stress in ketamine model of schizophrenia

Authors: P. A. RODRIGUES[1], G. M. ANDRADE[1], M. T. S. TREVISAN[2], V. S. RAO[1], *F. SANTOS[1]
[1]Physiol. and Pharmacol., [2]Organic and Inorganic Chem., Federal Univ. of Ceará, Fortaleza, Brazil

Abstract: Accumulating evidence indicates that mangiferin (MGF), a natural xanthone by virtue of its antioxidant and anti-inflammatory properties is neuroprotective. Here we sought to verify the neurocytoprotective role of MGF on cultured rat primary mesencephalic cells exposed to 6-hydroxydopamine (6-OHDA) *in vitro*, and the MGFs anti-inflammatory potential in mouse model of ketamine-induced schizophrenia *in vivo*. MGF was extracted and isolated from the bark of *Mangifera indica* L**.** (Anacardiaceae) as per standard procedures. MTT (3[4,5-dimethylthiazole-2il]-2,5-diphenyltetrazolium bromide)-assay was performed to measure cell viability in mesencephalic cell cultures exposed to neurotoxin (6-OHDA, 40 µM). Schizophrenia was induced in mice by ketamine (50 mg/kg, i.p., twice a day, for 7 days). The treatment effects of MGF (50 mg/kg, p.o., for 7 days) were verified on locomotor behavioral changes in open-field test, and on the oxidant stress-related increase in lipid peroxidation (malondialdehyde) and interleukin-6 (IL-6) levels in brain tissues. MGF (10-100 µM) produced no *per se* effect on cell viability as measured by MTT assay, but significantly prevented the 6-OHDA-induced cell death

in a concentration-dependant manner. Acridine orange/ethidium bromide (AO/EtBr) staining confirmed the absence of 6-OHDA-induced morphological changes characteristic of apoptosis/necrosis. In open-field test, ketamine-induced impaired locomotor activity and behavioral changes such as grooming and stereotyped but not rearing were effectively ameliorated by MGF pretreatment. Also, ketamine-associated increase in brain tissue levels of IL-6 and MDA were significantly lowered in MGF pretreated mice. Mangiferin has a neurocytoprotective role related, at least in part, to an antioxidant and anti-inflammatory mechanism, which could be explored for more effective therapies of schizophrenia and other neurodegenerative diseases.

Title: Protective effect of curcumin against hemin-induced neurotoxicity in primary cultures of cerebellar granule neurons of rats

Authors: *S. GONZALEZ[1], S. GUZMAN-BELTRAN[2], J. PEDRAZA-CHAVERRI[1]
[1]Biol., UNAM, Mexico, Mexico; [2]Inst. Nacional de Enfermedades Respiratorias "Ismael Cosío Villegas", Mexico, Mexico

Abstract: Curcumin, a yellow pigment derived from Curcuma longa Linn, has attracted great interest during the past decades. Extensive studies documented that curcumin has diverse biological activities as anti-inflammatory, anticarcinogenic and antioxidant, among others. This work was designed to determinate the potential protective effect of curcumin on neurons in culture.
Primary cultures of cerebellar granule neurons (CGNs) from rats were treated with curcumin (10-50 μM) to evaluate its cytotoxicity by MTT reduction method. Then, we evaluated if this compound has protective effect. CGNs were pretreated with curcumin and subsequently exposed to hemin as a generator of oxidative stress and cell viability was monitored.

It was found that curcumin (1-30 μM) was unable to modify cell viability significantly. In contrast, hemin alone (30 μM) decreased viability to 50% but when CGNs were pretreated with curcumin (5, 10 and 15 μM) before the addition of hemin, the viability diminished 12% compared with curcumin or control. In addition, it was found that curcumin induced heme oxygenase-1 (HO-1) in a concentration and time-dependent way. Furthermore, HO activity was directly correlated with the amount of intracellular protein. Curcumin protection was blocked by the HO inhibitor tin mesoporphyrin. Moreover, the content of reduced glutathione (GSH) was increased when the cells were incubated with curcumin alone and this increase was diminished by buthionine sulfoximine, an inhibitor of GSH synthesis. Hemin decreased GSH content and this decrease was blocked when CGNs were exposed to curcumin and hemin simultaneously, It is concluded that curcumin has a protective role against hemin toxicity and that HO activity, HO-1 expression and GSH are involved in this protective effect.

Abstract: Oxidative damage induced by reactive species (RS) has a relevant pathophysiological role in several types of human diseases. In order to neutralize these RS, the cells have developed a complex biochemical redox mechanism, consisting of both enzymatic and non-enzymatic components. Moreover, foods, particularly fruits and vegetables, also have an important role in maintaining physiological redox equilibrium. In this context, grapes are rich in phenolic compounds, such as flavonoids. The objective of this study was to investigate the *in vitro* neuroprotective effect of conventional and organic white grape juices on oxidative stress induced by sodium azide in cerebral cortex of rats of 10-day-old-rats. Cerebral cortex was homogenized and preincubated with 40% (w/v) conventional or organic white grape juices, furthermore the brain was incubated for 1 h with 5 mM sodium azide the presence or absence of 40% (w/v) conventional or organic white grape juice. The assays of acid reactive species (TBARS), sulfhydryl content and the activity of the antioxidant enzymes catalase (CAT) and superoxide dismutase (SOD) were performed. Sodium azide was able to enhance lipid peroxidation (TBARS) and to reduce the non-enzymatic antioxidants defenses (sulphydryl) in cerebral cortex of rats. Moreover sodium azide inhibited the activity of CAT and SOD. Conventional and organic white grape juices were able to prevent the effects caused by sodium azide in all assays, except the SOD activity. These results indicate that sodium azide induces oxidative stress in cerebral cortex of young rats and that conventional and organic white grape juices exhibit antioxidant properties capable of preventing the oxidative damage caused by this compound.

Title: Antioxidant and neuroprotective effect of purple grape juice in rats supplemented with high fat diet

Authors: *C. S. FUNCHAL[1], M. G. CARDOSO[1], N. MEDEIROS[1], D. DOS SANTOS LACERDA[1], D. C. DE ALMEIDA[1], C. D. DESTRI[1], E. R. DA SILVA[1], J. P. HENRIQUES[2], R. GOMEZ[2], C. DANI[1]
[1]Ctr. Universitário Metodista, Porto Alegre, Brazil; [2]Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil

Abstract: The consumption of foods and beverages containing phenolic compounds have been reported due to the benefits they produce on human health. Among these, stands out the grape juice. The Serra Gaucha is described as the most important wine region of Brazil. Regarding cultivars widespread in the Serra Gaucha, about 90% of the area is occupied by vines of *Vitis labrusca* cultivars, with a predominance of Isabel, Bordô and Concord that are more rustic and productive in relation to *Vitis vinifera*. The objective of this study was to investigate the antioxidant and neuroprotective effect of chronic use of purple grape juice (organic and conventional) from Bordô variety on oxidative stress in different brain regions of rats supplemented with high fat diet (HFD) for three months. A total of 40 male rats (21-day-old) were randomly divided into four groups. Group 1 received a standard diet and water, group 2 HFD and water, group 3 HFD and conventional grape juice (CGJ), and group 4 HFD and organic grape juice (OGJ). All groups had free access to food and drink and after three months of treatment the rats were killed by decapitation and the cerebral cortex, hippocampus and cerebellum isolated and homogenized on ice for oxidative stress analysis. The results demonstrated that HDF enhanced lipid peroxidation (TBARS) in cerebral cortex and hippocampus and that only OGJ was able to prevent this increase. HDF also increased protein damage measured by the carbonyl assay in cerebral cortex and hippocampus and that CGJ and OGJ were able to prevent this enhance. On the other hand, HDF reduced the non-enzymatic antioxidants defenses (sulphydryl) in cerebral cortex and cerebellum and both CGJ and OGJ were able to prevent this inhibition. Therefore, we conclude that the HFD induced oxidative stress in the brain of rats and that the chronic use of purple grape juice was able to prevent these oxidative alterations.

Title: The effect of proton particle radiation and pomegranate treatment on behavior in male and female wildtype mice

Authors: *M. S. DULCICH, E. THORNDYKE, J. RUBINSTEIN, N. MISTRY, R. E. HARTMAN
Psychology, Loma Linda Univ., LOMA LINDA, CA

Abstract: Astronauts have traveled outside Earth's atmosphere into lower earth orbit (LEO) and beyond for decades. However, these individuals are constantly exposed to ionizing radiation that may have deleterious effects on physical and mental health. With plans to extend space travel beyond LEO for longer durations (i.e., manned expeditions to Mars), the radiation exposure will increase. Because of the complex behaviors and cognitive functions required for mission completion and survival, the long-term effects of ionizing radiation on the brain and behavior for both male and female astronauts must be explored. Previous research indicates that males and females may respond differently to radiation exposure. Furthermore, some evidence suggests that antioxidants may offer some protection against the cellular effects of radiation, and research from our lab suggests that dietary sources of antioxidant polyphenols (such as pomegranate juice) may provide significant neuroprotection against Alzheimer's neuropathology, stroke, and traumatic brain injury. A diet enriched with polyphenols may confer enough protection from the effects of radiation to maintain the complex cognitive and fine motor skills required by astronauts. Ninety-six C57/BL6 mice (half receiving dilute pomegranate juice and half receiving dilute sugar water as a control) were irradiated with 2 Gy proton radiation (1-2 Gy/min), and post-radiation behaviors (activity, motor skills, spatial learning, anxiety, and learned helplessness) were assessed two months later. Proton irradiation was associated with more learned helplessness in the tail suspension test and the pomegranate diet significantly ameliorated those deficits. The pomegranate diet also ameliorated radiation-induced relational learning deficits in the spatial water maze task for females, but not males. Finally, control diet males, but not pomegranate diet males displayed worse coordination and balance on the rotarod than females. Thus, a pomegranate-enriched diet conferred protection from the effects of proton radiation in terms of learned helplessness (depression-like behaviors), and spatial learning in the water maze test (females only). Analysis of the effects of pomegranate juice supplementation on hippocampal neurogenesis after proton irradiation, as well as behavioral performance on the balance beam and openfield activity tests is currently underway. Overall, it appears that proton irradiation, such as that which may occur during long space flights, may cause a different pattern of behavioral deficits in males than females, and that a pomegranate enriched diet may confer protection against some of those effects.

Title: Dietary omega-6 polyunsaturated fatty acid deficiency reduces lipopolysaccharide-induced changes in behavior sickness and brain arachidonic acid inflammatory response

Authors: *A. TAHA, Y. CHEON, H. C. BLANCHARD, V. KELESHIAN, E. RAMADAN, M. CHEN, L. CHANG, S. I. RAPOPORT, J. S. RAO
Natl. Inst. on Aging, NIH, Bethesda, MD

Abstract: The omega-6 polyunsaturated fatty acid (n-6 PUFA), arachidonic acid (AA, 20:4n-6), is a precursor of prostaglandins, leukotrienes, and related compounds that have important roles in mediating the brain's innate inflammatory response to cytokines, which have been implicated in neuropsychiatric and neurodegenerative disorders. AA is released from the *stereospecifically numbered*-2 position of membrane phospholipids by AA-selective calcium-dependent cytosolic phospholipase A_2 ($cPLA_2$). The AA cascade can be activated in rodents with the bacterial endotoxin, lipopolysaccharide (LPS), which causes neuroinflammation and a characteristic depressive-like sickness behavioral profile. This study tested the hypothesis that dietary n-6 PUFA deprivation, which limits the supply of AA to the brain, would reduce LPS-induced AA-mediated neuroinflammation and associated changes in behavioral sickness. Male Fischer rats were fed an n-6 PUFA adequate diet (control, 6% of energy) or an n-6 PUFA deficient diet (0.5 % of energy) for 15 weeks, after which, they were infused with LPS (250 ng / hr) intracerebroventricularly into the 4th ventricle for 2 days using a mini-osmotic pump. Two days after infusion, behavioral sickness was scored, and the incorporation rate of intravenously infused unesterified ^{14}C-AA into brain phospholipids (an established marker of neuroinflammation). Dietary n-6 PUFA deprivation attenuated LPS-induced increases in the rate of ^{14}C-AA incorporation into brain phospholipid ($P < 0.05$ for main effect of LPS and diet by two-way ANOVA). This was associated with a significant decrease in behavioral sickness scores, which were increased by LPS infusion in control rats ($P < 0.05$). Because the AA incorporation rate is a quantitative marker of neuroinflammation, our results suggest a direct anti-inflammatory effect of dietary n-6 PUFA deprivation, in association with reduced behavioral

sickness. Thus, lowering dietary n-6 PUFA consumption in humans from estimated current intakes of 7% of energy to clinically achievable levels of 0.5~1% of energy, might increase resistance against pro-inflammatory insults to the brain or reduce the pathological neuroinflammation reported in neuropsychiatric and neurodegenerative diseases.

Title: Microglia ctivation induces axonal injury in corpus callosum

Authors: J. ZHANG, J. LIU, J. KRUCHOWSKY, H. S. FOX, *H. (. XIONG
Univ. of Nebraska Med. Ctr., OMAHA, NE

Abstract: Cumulative evidence from both autopsy and animal models of white matter tract disorders such as multiple sclerosis and amyotrophic lateral sclerosis suggest an involvement of activated microglia in nerve fiber injury. The activated microglia was also observed in subcortical white matter of both HIV-infected human subjects and SIV-infected monkeys. Whether the activated microglia induces axonal injury in corpus callosum (CC) remains to be determined. In this study, we examined if lipopolysaccharide (LPS)-activated microglia produce axonal injury by Western blot detection of β-amyloid precursor protein (β-APP) and electrophysiological analysis of compound action potentials (CAPs) in rat CC. For Western blotting, the CC slices were treated with different doses of LPS in oxygenated artificial cerebrospinal fluid for 12 h before CC dissection and protein extraction. Our results showed that treatment of the CC slices with LPS resulted in microglia activation and β-APP accumulation as illustrated by a significant increase of β-APP density when compared with the β-APP density obtained from untreated control CC slices, suggesting that LPS-activated microglia produced axonal injury in the CC. In parallel, electrophysiological studies revealed that treatment of CC slices with LPS significantly reduced input-output (I/O) responses as determined by measurement and analysis of CAP amplitudes. This LPS-associated reduction of I/O responses in

the CC was attenuated by RS-LPS, a toll-like receptor 4 (TLR-4) competitive antagonists, indicating activation of microglia by LPS resulted in a reduction of I/O responses. In all cases, LPS activation of microglia was judged by morphological changes visualized with fluorescent microscope by using Iba-1 immuno-fluorescent staining. Taken together, these results demonstrated that activated microglia induces axonal injury in the CC.

Title: Role of exercise in the reduction of inflammatory mediators in painful diabetic neuropathy

Authors: J. MEYERS[1,2], C. GALLOWAY[1,2], *M. CHATTOPADHYAY[1,3]
[1]Neurol., Univ. of Michigan, ANN ARBOR, MI; [2]Neurol., VAAAHS, Ann Arbor, MI; [3]Neurol., VAAAHS, An Arbor, MI

Abstract: Painful neuropathy is a significant complication in diabetic patients. Previous evidence suggests that proinflammatory cytokines may play a role in pain perception. We found in this study that regular exercise decreased painful neuropathy in the Type 1 model of diabetic animals by reducing inflammatory markers in the nervous system that are responsible for the alterations in pain perception in diabetic animals. Type 1 model of streptozotocin-diabetic animals were placed in motorized running wheels for sixty minutes per day, five days a week, starting at one week of diabetes and up to six weeks after diabetes. Behavioral measures of Hargreaves test to assess the thermal pain threshold, acetone spray to access cold allodynia and mechanical stimulation by the Randall-Selitto method to access nocifensive responsiveness were performed at two-week intervals after the onset of diabetes. Finally, animals were euthanized for collection of tissues and for further analysis of inflammatory mediators. After analysis of the results, we confirmed our hypothesis that exercise alleviated the pain related behaviors. There were significant changes in the mechanical hyperaglesia testing. The pain threshold of the control animals were 101 ± 5.3 g, whereas it was decreased in the diabetic sedentary group: 57 ± 1.8 g and the threshold improved in the diabetic exercise group: 87 ± 4.95 g. The latency to

withdraw from the cold stimulus was significantly decreased in diabetic sedentary group compared to control sedentary animals (diabetic 3.89 ± 1.89 sec; control 14.29 ± 1.63 sec) whereas diabetic exercise group showed improved latency to withdraw from the stimulus (17.44 ± 8.1 sec) but there was no change in the thermal hyperalgesia between control (12.14 ± .75 sec), diabetic sedentary (12.13 ± 1.56 sec) and diabetic exercise (12.60 ± 0.5 sec). On the basis of biochemical analyses of the tissues, exercise reduced the up-regulation of proinflammatory cytokines, which may directly correlate with the pain in the diabetic animals. Overall, this research suggest that exercise may provide an alternate route of treatment for painful neuropathy in Type 1 diabetic animals by decreasing the use of pain medication and provide a more useful and efficient way of management of pain.

Title: Effect of calcium-independant phospholipase A2 group VIA (iPLA2β) deficiency on enzymatic markers of arachidonic cascade and inflammation in old mice.

Authors: *H. BLANCHARD[1], A. Y. TAHA[1], Y. CHEON[1], H. KIM[1], J. TURK[2], S. I. RAPOPORT[1]
[1]NIH/NIA-BPMS, Bethesda, MD; [2]Sch. of Med., Washington Univ., Saint Louis, MO

Abstract: Calcium-independant phospholipase A2 group VIA (iPLA2β) participates in the remodeling of phospholipids by releasing polyunsaturated fatty acids, particularly docosahexaenoic acid (DHA) from the sn-2 position of membrane phospholipids. iPLA2β mutations occur in infantile neuroaxonal dystrophy (INAD) and dystonia-parkinsonism. We reported in 4-5 month-old iPLA2β-/- mice with minimal neuropathology compared to wild type that brain DHA metabolism was reduced while markers of arachidonic acid (ARA) metabolism were elevated. DHA metabolites have anti-inflammatory properties in the brain, whereas ARA is a precursor of pro-inflammatory eicosanoids. We hypothesized that iPLA2β deficiency triggers an imbalance between DHA and ARA metabolism in aged mice, and would promote inflammation and neuronal loss in the brain. Male iPLA2β-/- and wildtype mice were killed at 15-19 months of age and RT PCR and Western blotting were performed on whole brain homogenate. Results showed that phosphorylated ARA-releasing cytosolic PLA2 was increased

significantly in iPLA2β-/- mice, whereas other ARA cascade markers were unchanged (secretory PLA2, COX-2, mPGES). We found no significant change in pro-inflammatory cytokines expression (TNFα, Il-1β) or in synaptic markers (drebrin, synaptophysin). This study showed that iPLA2β deficiency in old mice leads to an elevation of ARA metabolism but does not trigger neuroinflammation or synaptic loss, suggesting that the neurodegeneration observed in these mice is not associated with neuroinflammation. It would also be of interest to assess localized synaptic integrity and to quantify downstream DHA and ARA metabolites. Title: Intravenous injection of the anti-inflammatory protein TSG-6 reduces neural damage after traumatic brain injury in mice

Authors: *J. WATANABE, D.-K. KIM, D. PROCKOP
Inst. for Regenerative Med., Texas A&M Hlth. Sci. Ctr., Temple, TX

Abstract: Administrations of mesenchymal stem/stromal cells (MSCs) were previously reported to produce beneficial effects in a series of disease models, including ischemic and traumatic injury to the central nervous system. In several models, the beneficial effects were in part explained by the MSCs being activated in vivo to express the anti-inflammatory protein TNF-α-stimulated gene/protein 6 (TSG-6). Here, recombinant TSG-6 protein was intravenously administrated in an experimental mouse model of traumatic brain injury. TSG-6 decreased the blood brain barrier leakage and the loss of tissue from the cerebrum and hippocampus. TSG-6 also decreased neutrophil extravasation, and significantly reduced expression of matrix metalloproteinase 9 (MMP9) by the infiltrated neutrophils and endothelial cells of the brain. The

data suggested that TSG-6, an anti-inflammatory protein produced by MSCs in response to injury signals, can provide an effective therapy for TBI.

Title: Differential signaling of CCL5 in retinal ganglion cells in the microbead occulsion model of glaucoma

Authors: *D. S. DUNCAN[1], A. C. REHORN[1], G. L. DAVIS[2], R. M. SAPPINGTON[1]
[1]Vanderbilt Eye Inst., [2]Interdepartmental Grad. Program, Vanderbilt Univ., Nashville, TN

Abstract: Glaucoma is one of the leading causes of blindness worldwide, where increased intraocular pressure in the eye results in retinal ganglion cell (RGC) death. To date, therapies developed lower elevated intraocular pressure; however these therapies do not directly prevent the death of RGCs. Inflammation of the eye, the release of inflammatory cytokines and chemokines by retinal glial cells, also contributes to the ensuing neuroinflammation and neurodegeneration in glaucoma. Thus, understanding the inflammatory mechanisms that influence RGC function and interactions with retinal glial cells may provide insight into glaucomatous pathology and the development of more effective therapies. Our laboratory has previously shown that retinal microglia upregulate CCL5 in response to elevated hydrostatic pressure. Therefore in this study, we examined the expression and localization of CCL5 and its receptors CCR3 and CCR5 in an acute murine model of glaucoma. We performed immunohistochemistry to assess the expression and localization of CCL5, CCR3 and CCR5 in retinas of 4 and 8 month old C57BL/6 mice in the acute microbead occlusion model. We co-labeled vertical retinal paraffin sections and whole mount retinas with CCL5, CCR3 and CCR5,

in addition to a cell-type specific marker for RGCs (SMI-31) to assess expression in RGCs and label intensity was used to quantify expression in both the central and peripheral retina. CCL5, CCR3 and CCR5 expression was detected in multiple layers of the retina in normal C57BL/6 mice. Furthermore, we observed that CCL5 signaling molecules are constitutively expressed in the ganglion cell and nerve fiber layers. Using SMI-31 co-labeling for anatomical localization, CCL5 and CCR5 were restricted to RGC somas and axons. In microbead-injected eyes, CCL5 intensity increased in both the ganglion cell and nerve fiber layers in the inner and outer retina of microbead-injected eyes compared to saline-injected eyes of 4 and 8 month old mice. CCR3 expression was significantly decreased in the inner retina of microbead-injected eyes, as compared to saline-injected eyes. This decrease was primarily associated with RGCs, as evidenced by a reduction in CCR3 in the ganglion and nerve fiber layers. Similar to CCR3, CCR5 expression also decreased in RGCs following elevated intraocular pressure in microbead-injected eyes. These data support a functional role for constitutive and inducible CCL5 signaling in RGCs. Additionally, the differential effects of elevated intraocular pressure further provide evidence that CCL5 is relevant to glaucomatous pathology and the inflammatory microenvironment relating to RGC dysfunction and RGC-glial interactions.

Title: P38MAPK, a mediator of hypoxia-induced cerebrovascular inflammation

Authors: D. TRIPATHY, A. SANCHEZ, X. YIN, J. LUO, J. MARTINEZ, *B. B. MILLER, P. GRAMMAS
Pathology, TTU Hlth. Sci. Ctr., Lubbock, TX

Abstract: Vascular perturbations and hypoxia are increasingly implicated in Alzheimer’s disease (AD) pathogenesis. Cerebral hypoxia induces a large number of inflammatory proteins in brain endothelial cells via signaling pathways that have not been defined. The p38 mitogen-activated

protein kinase (MAPK) signaling system has been implicated in endothelial injury and inflammation. The objective of this study is to determine the role of p38 MAPK signaling in hypoxia-mediated effects on brain endothelial cells. Exposure of brain endothelial cells to hypoxia (2-6 hours) shows a time-dependent increase in the phosphorylated (active) form of p38 MAPK (pp38 MAPK). Examination of these cultures at 6 hours hypoxia shows that inflammatory proteins such as monocyte chemoattractant protein-1, interleukin-6, and thrombin are significantly elevated and that the selective p38 MAPK inhibitor SB203580 significantly reduces the hypoxia-mediated increase in their expression. Expression of pp38 MAPK is also elevated in the cerebromicrovasculature of rats treated with 10 mg/kg $CoCl_2$ which induces hypoxia in vivo. Finally, western blot analysis of both human samples and tissues from AD transgenic mice show that pp38 MAPK is increased isolated brain vessels derived from AD brains compared to control-derived vessels. These data demonstrate that pp38MAPK is a key regulator of hypoxia in the cerebrovasculature and suggest that control of this signaling pathway could have therapeutic value in AD and other disorders where hypoxia is involved. Title: Grey matter pathology during the course of EAE in Dark Agouti rats

Authors: D. MORSALI[1], *J. O'BRIEN[2], W. LEE[3]
[1]Neurol., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX; [2]Univ. Texas Hlth. Sci. Cntr Houston, HOUSTON, TX; [3]Neuroinflam., Univ. Col. London, London, United Kingdom

Abstract: Objectives
Recent quantitative magnetic resonance imaging studies in multiple sclerosis (MS), a progressive disease of the central nervous system involving inflammatory processes, demyelination and irreversible degeneration of the axons of neurons, indicate that grey matter atrophy occurs from the earliest stages of disease. It develops faster than white matter atrophy, and is more related to physical disability and cognitive impairment than T2 and T1 white matter lesion volumes. However, the majority of studies on the experimental models of MS, experimental autoimmune

encephalomyelitis (EAE), have largely overlooked the events occurring in the grey matter. In this study, we have explored grey matter pathology at five stages throughout the course of EAE in Dark Agouti rats.

Methods

EAE in DA rats was induced by subcutaneous immunisation with recombinant myelin oligodendrocyte glycoprotein (rMOG). Animals were culled at five different time points along the disease course ('Preinduction (naïve)', 'Predisease', 'Peak of disease', 'Remission', and 'Relapse') and the tissue was processed immunohistochemically for motor neurons, astrocytes, and perivascular macrophages. The neurological deficit was assessed daily for seven days on a 10 point scale. Terminal electrophysiological examination was performed under ketamine (90mg/kg)/xylazine (10mg/kg) anaesthesia to record motor neuron excitability (F wave), followed by a cardiac perfusion for histological analysis.

Results

The number of activated astrocytes and perivascular macrophages was significantly higher at the 'Peak of disease' compared to 'relapse' or other time points along the disease course in animals with EAE. This occurred despite EAE animals exhibiting the same intensity of neurological deficits at both 'Peak of disease' and 'relapse'. Interestingly, the number of intact motor neurons significantly decreased from 'Peak of disease' onwards. The latter occurred in conjunction with declining motor neuron excitability, further confirming motor neuron loss of function.

Conclusion

Differences in grey matter pathology between 'Peak of disease' and 'relapse' in EAE indicate that the underlying mechanism(s) of pathology at these two critical stages are different. Our results emphasize an important role played by grey matter pathology in EAE.

Title: Protective effects of low alcohol concentrations against inflammatory-mediated toxicity in neuroblastoma-derived cells

Authors: Y. CHIN, D. O. BROWN, R. E. TAYLOR, *Y. TIZABI
Pharmacol., Howard Univ. Col. Med., Washington, DC

Abstract: Detrimental effects of alcoholism and neurotoxic effects of higher alcohol concentrations in in-vitro models are well documented. In contrast, epidemiological and preclinical studies suggest positive effects of low alcohol concentrations. Thus, protective effects of alcohol in cultured neuroblastoma-derived (SH-SY5Y) cells that were exposed to salsolinol, an endogenous neurotoxin resembling MPTP, have been reported. Since inflammatory processes may be an important contributory factor in neurodegenerative diseases, we were curious to determine whether low alcohol concentration may also provide protection against inflammatory-mediated toxicity. For this purpose we used two inflammatory cytokines (TNF-alpha and IL1-beta) as well as lipopolysaccharide (LPS), a chemical expressed on the outer membrane of gram-negative bacteria to induce cellular toxicity. Exposure of SH-SY5Y cells to 30 ug/ml of either TNF-alpha or IL1-beta for 72 h resulted in approximately 35% toxicity as determined by MTT (3,[4,5-dimethyliazol-2-yl]-2,5-diphenyltetrazolium bromide) assay. Similar exposure to 300 ug/ml LPS resulted in approximately 40% toxicity. Combining the two cytokines alone or together with LPS did not result in any additional toxicity. Pre-treatment of cells with ethanol (0.1-50 mM) resulted in dose-dependent protection against all 3 toxicants with maximal protection at 50 mM ethanol. None of the alcohol concentrations on their own resulted in any cellular toxicity. These preliminary results suggest protective effects of low alcohol concentrations against inflammatory mediated neurotoxicity. Further verification of the anti-inflammatory effects of ethanol in other in-vitro and in-vivo models and elucidation of the protective mechanism may provide therapeutic potential for low alcohol concentrations in neuroinflammatory-mediated diseases.

Title: Tau hyper-phosphorylation alters CX3CL1 levels and induces autophagic defects and 4E-BP signaling: a possible link between inflammation and autophagy

Authors: *M. HEBRON[1], I. LONSKAYA[2], N. ALGARZAE[2], N. DESFORGES[2], C. MOUSSA[2]
[1]Washington, DC; [2]Georgetown Univ., Washington, DC

Abstract: Several neurodegenerative diseases are characterized by accumulation of hyper-phosphorylated Tau (p-Tau) and neuro-inflammation. To measure inflammatory markers and p-Tau clearance, our lab generated lentiviral gene transfer animals by expressing $A\beta_{1-42,}$ wild type Tau, and P301L in the cortex of two-month-old male Sprague-Dawley rats. P301L resulted in significantly higher levels of p-Tau, compared to wild type Tau injected animals. A significantly higher level of TNF-α and IL-6 were detected in Tau and P301L expressing animals compared to LacZ, but CX3CL1 levels were significantly higher in Tau expressing animals compared to P301L. Lentiviral expression of $A\beta_{1-42}$ remarkably increased p-Tau, TNF-α levels, and caspase-3 activation at four weeks compared to two weeks post-injection, suggesting that the additive effects of $A\beta_{1-42}$ and p-Tau accelerate cell death. Tau resulted in increased levels of ADAM-10, ADAM-17, and soluble CX3CL1 levels. In correlation, CX3CL1 levels were also significantly increased in $A\beta_{1-42}$ expressing animals at four weeks post-injection, when p-Tau was detected. The increase in CX3CL1 levels, at four weeks post injection in $A\beta_{1-42}$ expressing animals, was associated with increased microglial activation, independent of astrocytes. Assessing the overall effects of autophagy revealed an increase in HDAC6 levels and activation of LC3, without autophagic clearance. Subcellular fractionation confirmed the accumulation of p-tau in autophagosomes (AV-20), which resulted in autophagic vacuole accumulation in the cytosol. Tau increased mTOR activity and resulted in the activation of 4E-BP signaling. Accumulation of p-Tau alters normal autophagy but inhibits autophagic clearance, perhaps due to the destabilization of microtubules and impairement of axonal transport. Accumulation of p-Tau is linked to changes in inflammatory responses, including CX3CL1 signaling, suggesting a possible cross-talk between amyloid-stressed neurons and microglia.

Title: Electroencephalograph (EEG) implantation with isoflurane anesthesia 7 days prior to brain injury induced by soman significantly reduces neuropathology and inflammation in rats.

Authors: *E. A. JOHNSON, T. L. DAO, J. F. IRWIN, J. A. LEUSCHNER, S. W. KASKI, R. K. KAN

Abstract: Status epilepticus (SE) can cause significant neuronal cell death as a consequence of acute exposure to potent acetylcholinesterase inhibitors such as soman (GD). The monitoring of SE is traditionally accomplished by implantation of cortical electrode probes under isoflurane anesthesia for electroencephalographic (EEG) recording with post-operative buprenorphine pain management. Anesthetics, such as isoflurane but not buprenorphine, can be neuroprotective when given prior to CNS insult, though these effects greatly diminish beyond 2 days. Therefore, to avoid unintended experimental effects from isoflurane preconditioning, a 7-day delay between surgery and experimental injury has been typically used. Here we describe a significant reduction in several inflammatory factors both in the brain and in circulation and a reduction in neuropathology following seizurogenic exposure to GD after a 7-day recovery period from EEG surgery in which isoflurane was used as the anesthetic. Levels of central and circulating inflammatory proteins were quantified using Luminex multiplex bead immunoassays up to 24 hours following SE onset in rats that either did or did not receive EEG surgery. Various factors involved with neuropathology were also compared between these groups. Significant differences were found in the magnitude and temporal expression of inflammatory and neuropathology associated proteins between EEG surgery and no surgery groups. These data show that even brief exposures (<20 min) to anesthetic amounts of isoflurane or the surgery itself 7 days prior to experimentation can significantly reduce the central and peripheral inflammatory response to brain injury. Therefore, longer recovery times following surgery may be necessary to reduce unintended secondary surgery effects on neuroinflammation studies.

Title: Cannabinoids prevent the amyloid β-induced hemichannel activity in neurons and glial cells

Authors: *J. A. ORELLANA[1], K. F. SHOJI[2], J. C. SÁEZ[2], C. GIAUME[3]
[1]Dept. de Neurología, Pontificia Univ. Católica De Chile, SANTIAGO, Chile; [2]Dept. de Fisiología, Pontificia Univ. Católica de Chile, Santiago, Chile; [3]CIRB, UMR CNRS 7241/ INSERM U1050, Col. de France, Paris, France

Abstract: The mechanisms involved in Alzheimer's disease (AD) are not completely understood and how glial cells contribute to this neurodegenerative disease remains to be elucidated. Recently we showed that amyloid-β peptide (Aβ) increase hemichannel activity in microglia, astrocytes and neurons, affecting neuronal viability. Because cannabinoids (CB) have anti-inflammatory properties and their receptors (CB-R) are largely expressed in microglia and astrocytes, we investigated upon primary glial cell cultures and hippocampal slices, the effects of CBs (WIN, 2-arachidonyglycerol, and methanandamide) on (i) Aβ-induced hemichannel activity in brain cells; (ii) Aβ-induced release of glutamate and ATP from glial cells and (iii) Aβ-induced neuronal death. Cultures of microglia, astrocytes or neurons as well as acute hippocampal slices were treated with 10 μM $A\beta_{25-35}$ for 72 h or 3 h, respectively. Hemichannel activity was monitored by single channel recordings and by time-lapse ethidium uptake while neuronal death was assessed by Fluoro-Jade C staining. We found that WIN, 2-arachidonyglycerol and methanandamide strongly inhibited the $A\beta_{25-35}$-induced hemichannel activity in glial cells, but not in neuronal cultures. Importantly, the $A\beta_{25-35}$-induced release of glutamate and ATP via glial cell hemichannels was inhibited by CBs, reducing neuronal death. Pharmacological characterizations of the CBs actions on $A\beta_{25-35}$-induced changes in glial hemichannel activity, glial glutamate/ATP release and neuronal revealed that these effects were mainly mediated through the CB1-R activation, although some partial action was observed via CB2-R activation. Altogether these data support the idea that under pro-inflammatory conditions, cannabinoids exert, through activation of different sub-types of glial CB-Rs, an inhibitory effect on glial hemichannel activity, which result neuroprotective and open novel avenues for alternative treatments for AD.

Abstract: Glia cells (astrocytes and microglia) play an important role in mediating immune processing in the central nervous system (CNS). Evidence indicates glial cell activation is directly linked to a variety of CNS diseases. Elucidating the impact of inflammatory processes on neurodegeneration has been a challenge; efforts have focused on biomarker identification. The peripheral benzodiazepine receptor (PBR) or translocator protein (TSPO) is a key biomarker used in the development of radiotracers for examining activated microglia, reactive gliosis, brain injury and other inflammatory processes. Here, quantitative autoradiography with [^{3}H]**PBR28** measured the change in TSPO density as an inflammatory response to neurofibrillary tangle pathology in Tg4510 mice and kainic acid (KA) lesioned rats. First, the dissociation constant (K_d) was determined using saturation binding and Scatchard analysis; K_d values were ~0.4-0.9 nM in frontal cortex, hippocampus, choroid plexus, thalamus and cerebellum of both rat and mouse. Tg4510 mice (3 and 6 months) and age-matched wild type (WT) cohorts were utilized for PBR autoradiography quantification of TSPO receptor expression. A high density of TSPO was detected in 3 month old Tg4510 vs. age-matched WT mice only in the hippocampus (fmol/mg tissue): 433 vs. 322 (p=0.004). Extensive regional increases in TSPO levels were found in 6 month old Tg4510 mice vs. age matched WT group in the frontal cortex 568 vs. 335 (p=0.011); pituitary gland 1506 vs. 1105 (p=0.034); thalamus 240 vs. 193 (p=0.034); and cerebellum 549 vs. 463 (p=0.029). These data were consistent with the reported temporal change of neurofibrillary tangles pathology in this transgenic model. As an additional model of neuroinflammation, adult male rats were given either intraperitoneal PBS or KA (12 mg/kg); KA-treated animals reached high seizure scores within 3 hours. 7 days post KA injection rats were euthanized and brains harvested for [^{3}H]**PBR28** autoradiography studies. A significant

increase in TSPO levels was found in rats receiving KA vs. controls in the frontal cortex (572 vs. 188, p=0.014), thalamus (1127 vs. 193, p=0.0003), hippocampus (1152 vs. 237, p=0.0002), and choroid plexus (3275 vs. 2565, p=0.011). Immunohistochemistry (IHC) staining on adjacent sections from Tg4510 mice and KA-treated rats was carried out using the microglia marker ionized calcium binding adaptor molecule 1 (Iba1) and the astrocyte marker glial fibrillary acidic protein (GFAP). IHC staining in the hippocampus, frontal cortex, thalamus, cerebellum and brain stem showed glial cell activation correlated with the [^{3}H]**PBR28** autoradiography binding.

Title: Fibrillar alpha-synuclein elicits complex morphofunctional activation states in microglia

Authors: *D. A. JOSEPH, L. R. FENG, L. CORTES-AVELLANEDA, K. A. MAGUIRE-ZEISS
Georgetown Univ., WASHINGTON, DC

Abstract: Parkinson’s disease (PD), an age-related neurodegenerative disorder, is characterized by the loss of dopamine neurons in the substantia nigra, the accumulation of alpha-synuclein (SYN) in Lewy bodies and neurites, and neuroinflammation. While the exact etiology of sporadic PD remains unknown, a growing body of evidence suggests that misfolded SYN promotes inflammation and oxidative stress with subsequent neurodegeneration. Microglia are the resident immune cells of the brain capable of quickly reacting to danger/damage associated molecular patterns (DAMPs) through activation of pattern recognition receptors (PRRs), such as Toll-like receptors (TLRs). When a proinflammatory pathway is initiated activated microglia release cytokines, chemokines and nitric oxide which if unchecked can adversely impact adjacent neurons. We have demonstrated that misfolded SYN containing SDS-resistant high

molecular weight and monomeric species promotes inflammation and alters the expression of TLRs1, 2, 3 and 7, suggesting that SYN acts as a DAMP. In order to determine the mechanism of activation we separated the misfolded SYN into HMW (~250 kDa) and LMW (~16 kDa) fractions. Using both primary microglia from C57 mouse cortices and BV-2 microglia we assessed morphofunctional activation using immunocytochemistry and quantification of proinflammatory cytokine gene expression, production, and release. Here we report upregulation of proinflammatory (TNF-α, IL-1β and MMP9) and alternative activation (Arg-1 and IL-10) profiles in HMW SYN-stimulated microglia. In contrast, LMW SYN does not promote microglial activation. We also show that conditioned media from SYN-activated microglia attenuates the neurite complexity of dopamine neurons indicating that these microglial secreted molecules are detrimental to neurons. Overall, these data suggest that SYN-directed microglial activation occurs through specific pathways that are dependent on the conformation of SYN. These TLR-mediated microglial responses to SYN open an avenue for novel PD therapies, where altering SYN structure would attenuate inflammation.

Title: Novel magnetic resonance imaging techniques to visualize inflammatory/degenerative mechanisms

Authors: *R. CLEMENTS, E. FREEMAN, J. BLANK, A. KHITRIN
Kent State Univ., Kent, OH

Abstract: Current therapies alter neuro-inflammatory/degenerative diseases (such as Multiple Sclerosis, MS), however, little is known about their impact on neuroprotection and repair. Further, the development of effective therapies for these important components of MS has been hampered by the lack of sensitive clinical response criteria. We propose new methods aimed at associating changes in magnetic resonance (MR) detectable white/gray matter disease activity with pathological outcomes enhancing our understanding of degenerative processes resulting in tissue atrophy. We present novel protocols for existing MR scanning systems providing the

ability to visualize structures that are impossible with current methods. Using techniques to concurrently stain and three-dimensionally analyze many cell types and structures related to auto-inflammatory pathology (glial cells, neurons, myelin, microvessels, infiltrates) and correlate these changes with existing and novel MR modalities will provide new ways of processing, acquiring, analyzing and understanding data from existing MRI hardware. Spinal cords from control mice and mice with induced experimental autoimmune encephalomyelitis (EAE) were subjected to MR imaging using standard protocols and newly developed MR imaging sequences. Novel imaging sequences were designed to resolve tissues with short T2 (invisible in conventional MRI) using new signal excitation methods. After MR acquisition, spinal cords were sectioned and immunofluorescently probed to concurrently label neurons, glial cells, microvessels, cellular infiltrates and myelin. 3D laser scanning microscopy and digital reconstruction were utilized to generate high resolution volumetric data. MR and multichannel microscopy data were co-registered and analyzed to identify novel cellular phenomena/structures related to autoimmune inflammatory diseases visible in the newly developed MR acquisition sequences that resolves tissue with a short T2.

Title: Ablation of protocerebral tract in crustacean induces both migration of hemocytes and activation of glia cells.

Authors: P. G. CHAVES DA SILVA[1,2], C. CORRÊA[3], *S. ALLODI[2]
[1]Programa de Biologia Celular e do Desenvolvimento, Inst. Ciências Morfológicas, UFRJ, Rio de Janeiro, Brazil; [2]Programa de Biologia Celular e do Desenvolvimento, Inst. Biofisica Carlos Chagas Filho, UFRJ, Rio de Janeiro, Brazil; [3]Faculdade de Medicina - Dept. de Clínica Médica, Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Circulating hemocytes are crucial in injury processes by participating in recognition, phagocytosis, melanization and cytotoxicity (Jiravanichpaisal, 2006). Likewise, microglial cells - specialized macrophages of the central nervous system - act as primary responding cells by producing a large number of pro-inflammatory factors, including nitric oxide (Saijo and Glass, 2011). In a previous paper of our laboratory, the protocerebral tract (PCT) of the crab *Ucides cordatus* was analyzed after extirpation of the eyestalk (Corrêa et al., 2005). In this paper we showed that among axons with morphologic aspects of axoplasmic degeneration, granular cells resembling hemocytes (blood cells) were seen. Based on this observation, we classified these cells and their participation in an acute degenerative process, 24 hours after lesion (Chaves-da-Silva et al., 2010). In the present work, our objective was to study the morphological and biochemical relationships between glial cells and hemocytes 48 hours after lesion (subacute response), as well as to study possible molecules released during the degenerative process. Analyzing the distal stump of injured PCT by immunohistochemistry, histochemistry, light and electron microscopies, and western blot, we observed a large number of IB4-positive cells (macrophages/microglia) when compared with control animals. These cells showed granules in the cytoplasm and were labeled for iNOS (inducible nitric oxide) and histamine. In the same region we observed an increasing number of cells labeled for GFAP (glial cells). Some of the cells containing granules (hemocytes) migrated further into the damaged tract when compared with the acute response (24 hours) PCT (Chaves-da-Silva et al., 2010). Electron micrographs of the PCT exhibited alterations in the morphologic aspect of the cells which infiltrated into the injured tract, when compared with the cells that surrounded the tract close to the connective tissue. Our results suggest that the presence of iNOS and histamine in the lesion site may be considered an important factor involved in the activation of hemocytes and/or glial cells attracted to the injury. In addition, we propose that there are two functionally different types of glial cells: GFAP positive cells, which respond to injury by changing their nuclei morphology and another, which maintains its morphology, as seen in normal conditions, and is not capable to express GFAP. These results show that hemocytes and glial cells have a critical role during degenerative processes, being essential to remove cellular debris and to organize the microenvironment for neuroregeneration.

Abstract: Cells of myeloid origin mediate immunological roles in the mature brain. Microglia, the resident innate immune cells, populate the central nervous system (CNS) early in development and continuously monitor parenchymal tissues. While monocytes do not infiltrate CNS tissues during normal conditions, in response to injury, circulating monocytes can, at least temporarily, engraft in the brain and contribute to neuroimmune responses. Identification and subsequent analysis of microglia and CNS-engrafted monocytes is difficult due to nearly overlapping protein expression patterns. Previous studies have utilized whole-body irradiation coupled with transfer of labeled bone marrow-derived hematopoietic progenitors to distinguish between brain resident and peripheral cells. However, this approach induces damage to the blood brain barrier and introduction of supraphysiological levels of uncommitted hematopoietic stem cells into the circulation, leading to exaggerated monocytic infiltration of CNS tissue. In the present study, we wanted to determine if pro-inflammatory, Ccr2-expressing, circulating monocytes engraft in CNS tissue in response to neuronal cell death. To accomplish this, we utilized novel animal models in which the open reading frame of Ccr2 was replaced by red fluorescent protein (RFP) cDNA, such that heterozygous mice have RFP-expressing Ccr2-positive cells and retain receptor function. Homozygous Ccr2rfp/rfp knockout mice, maintained on the C57BL/6 inbred background, were crossed to wild-type FVB animals to create F1 hybrid Ccr2 heterozygous (B6.FVB-Ccr2-RFP) mice. B6.FVB-Ccr2-RFP mice subjected to kainic acid (KA) experienced seizures and neuronal cell loss in the hippocampus. As expected, neuronal degeneration was accompanied by local microgliosis. However, KA-induced neuronal degeneration also induced robust infiltration of peripheral Ccr2-RFP-expressing monocytes. Strikingly, the infiltrating Ccr2-positive monocytes were encountered specifically in the hippocampus and were not encountered in other brain regions, suggesting that, like microgliosis, monocyte infiltrating was remarkably specific to injured brain sites. Our future studies will be designed to further characterize CNS-infiltrating monocytes during neuronal degenerative processes by examining the temporal sequence of neuronal cell loss, microgliosis and monocyte infiltration. In addition, the role of monocytes in the injured brain will be determined by inhibiting monocyte infiltration after KA exposure.

Title: IL-6 trans-signaling and neuroprotection of retinal ganglion cells in glaucoma

Authors: *H. M. CATHCART[1], C. R. FORMICHELLA[2], R. M. SAPPINGTON[2]
[1]Ophthalmology, Vanderbilt Univ. Med. Ctr., Nashville, ; [2]Ophthalmology, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: The cytokine IL-6 initiates pro- and anti- inflammatory signaling cascades through two receptors: membrane bound IL-6Rα (classical signaling) and soluble IL-6R (sIL-6R; trans-signaling). Both receptors interact with membrane bound gp130, a common signal transducer, causing downstream activation of transcription factors with the potential to modulate neuroinflammatory responses. The purpose of this study was to evaluate the neurobiological relevance of trans-signaling in the onset and progression of retinal ganglion cell (RGC) pathology in chronic and acute murine models of glaucoma. Using a co-immunolabeling assay, the presence of sIL-6R and transmembrane IL-6Rα were assessed simultaneously in vertical paraffin sections of retina, whole mount retina and optic nerve head. For this assay, two antibodies against IL-6Rα were used; the first is specific to the cytoplasmic peptide sequence, while the second is specific to the extracellular sequence. IL-6Rα was identified by co-localization of both antibodies whereas sIL-6R was revealed by the presence of only the extracellular antibody. Furthermore, IL-6Rα, sIL-6R, gp130 and soluble gp130 (sgp130) were quantified from soluble and trans-membrane protein isolated from whole retina and both fractions were analyzed using the Milliplex Map mouse soluble cytokine receptor immunoassay. In retina whole mounts from young and old mice exposed to chronic (DBA/2) and acute

(microbead injected C57BL/6) increase in intraocular pressure, we found that both forms of IL-6R were associated with SMI-31 or DAPI in RGCs. However, localization of IL-6Rα was primarily associated with RGC and astrocyte somas in control or PBS injected C57BL/6 mice, while strong sIL-6R labeling was associated with RGC axons and retinal vasculature in DBA/2 and microbead injected mice. The cytokine receptor immunoassay suggests that IL-6Rα concentration increased in old DBA/2 (9.70 pg/ml) retinas when compared to retinas from old C57BL/6 (6.88 pg/ml) mice. The immunoassay also revealed that both sIL-6R and IL-6Rα decreased in young DBA/2 (1.74 and 0.35 pg/ml) retinas when compared with concentrations from retinas of young C57BL/6 (5.42 and 4.99 pg/ml) mice. Gp130 concentrations were increased in young DBA/2 retinas (33.73 pg/ml; C57BL/6 11.24 pg/ml), while sgp130 concentrations were below the level of assay detection. These results indicate that sIL-6R is consistently associated with RGC axons in the retina and optic nerve head. The location and potential variability of sIL-6R expression within glaucomatous retinas is crucial to defining the role of sIL-6R in augmenting glial and neuronal responses in this inflammatory microenvironment.

Title: Evidence for neuroinflammation in the thiamine deficient rat

Authors: C. ALT[1], A. MANNING-BOG[2], E. V. SULLIVAN[3], *A. PFEFFERBAUM[4,3], N. M. ZAHR[3,2]
[1]Immunol. and Inflammation Group, [2]Neurosci., SRI Intl., Menlo Park, CA; [3]Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA; [4]SRI Intl. BN 168, MENLO PARK, CA

Abstract: Wernicke's Encephalopathy (WE), a disorder induced by thiamine (vitamin B1) deficiency (TD), is a concomitant of alcoholism, anorexia, and bariatric surgery. WE is

associated with focal pathology in brain regions, including the thalamus, mammillary bodies, and inferior colliculus. Many biological processes, such as inflammation, have been proposed to explain the selective neuronal loss observed in WE. To provide support for a role for neuroinflammation in TD, wild-type Wistar rats were fed TD chow; animals were also given either pyrithiamine (PYR, n=5) to induce TD, or thiamine (CON, n=5) to ensure they were thiamine replete. Following TD, the PYR group was discernible from the CON group by weight loss, piloerection, ataxia, and slowed righting reflex. Animals were euthanized after 12 days of treatment and extracted brain hemisections were either quick frozen in liquid nitrogen for cytokine protein analysis or placed in 4% paraformaldehyde for immunohistochemical analysis of glial activation. The levels of the pro-inflammatory cytokines TNF-α, IL-6, and IL1-β and the chemokine MCP-1 (i.e., CCL2) were quantified in the thalamus and inferior colliculus, structures vulnerable to TD. MCP-1 levels were significantly higher in the inferior colliculus of the PYR than CON group (p=.0077) and showed an insignificant trend in the thalamus (p=.1229). Evaluation of histopathology (astroglial activation determined by GFAP and microglial activation determined by Iba-1 immunoreactivities) may provide morphological support for biochemical evidence of inflammation in the inferior colliculus. These data support a previous finding reporting a role for secreted chemokines (i.e., MCP-1) in the pathophysiology of TD.

Title: Investigating the role of prostaglandin E2 mediated neuroinflammation in models of parkinsonism

Authors: *S. S. PRADHAN[1], J. JOHANSSON[1], Q. WANG[1], N. KO[2], A. MANNING-BOG[2], K. ANDREASSON[1]
[1]Stanford Univ., Stanford, CA; [2]SRI Intl., Menlo Park, CA

Abstract: Recent studies have identified non cell-autonomous mechanisms such as inflammation as major contributors to Parkinsonian disease (PD) pathology. Neuroinflammation in PD is primarily mediated by significant increases in reactive microglia, which secrete pro-inflammatory cytokines and chemokines and reactive oxygen and nitrogen species (ROS/RNS). The prostaglandin E2 (PGE2) receptors EP2 and EP4 can respectively amplify or dampen microglial inflammation in a disease setting. However the role of microglial EP2 and EP4 has not been studied in the context of PD. In this study we investigate the interaction between microglial PGE2 signaling and dopaminergic (DA) neuron degeneration in the MPTP neurotoxin model of Parkinsonism. We show that MPTP induced loss of DA neurons and striatal dopamine levels is correlated with an increase in activated microglia in the substantia nigra and striatum. Our data suggests that modulating EP2 and EP4 signaling in microglia influences dopaminergic neuron survival, loss of striatal DA neuron projections, and levels of striatal dopamine. Furthermore we show that PGE2 signaling regulates microglial oxidative stress and cytokine production in vitro. The data indicates that EP2 and EP4 receptors may interact with Parkinsonian mechanisms by regulating inflammatory pathways in microglia. Targeting PGE2 signaling may be a potential therapeutic avenue for PD and other neurodegenerative disorders with a neuroinflammatory component.

Title: Inhibition of tissue-type plasminogen activator expression does not ameliorate neuro-inflammation in forebrain-specific Cdk5 conditional knockout mice

Authors: *E. UTRERAS PURATICH[1,2], M. PROCHAZCOVA[2], A. TERSE[2], S. TAKAHASHI[3], A. B. KULKARNI[2]
[1]Univ. of Chile. Fac. of Sci., Santiago, Chile; [2]NIDCR, NIH, Bethesda, MD; [3]Dept. of Pediatrics, Asahikawa Med. Col., Hokkaido, Japan

Abstract: Cyclin-dependent kinase 5 (Cdk5) is essential for brain development and its deregulation is involved in neurodegenerative diseases. We reported earlier that the forebrain-specific Cdk5 conditional knockout (Cdk5 cKO) mice displayed early lethality at 3 weeks of age associated with neuronal migration defects, transient tremors, and growth retardation. The expression levels of the neuronal tissue-type plasminogen activator (tPA), a serine protease known to mediate microglial activation, were significantly increased in Cdk5 cKO mice. To delineate the specific role of tPA in the Cdk5 cKO phenotype, we generated Cdk5 cKO; tPA double knockout (2cKO) mice. Interestingly, 2cKO mice displayed a partial rescue in body weight gain and astrogliosis but still died at around 3 weeks of age, suggesting that increased expression of tPA observed in Cdk5 cKO mice does not contribute significantly to the pathological process that leads to astrogliosis and neurodegeneration. Furthermore, as compared to Cdk5 cKO mice, 2cKO mice also displayed increased expression of pro-inflammatory cytokines such as TNF-alfa, IL-6, IL-1 beta, IFN-gamma, OSM, LIF, and TGF-beta 1 in the brain cortex. Moreover, the CD68 levels, which are markers of microgliosis, were increased in 2cKO mice as compared with Cdk5 cKO mice. In conclusion, these results suggest that inhibiting tPA expression in Cdk5 cKO has no benefits for preventing its lethal phenotype associated with increased neuro-inflammation.

Title: The effect of the transcription factor Nurr1 in the adult dopaminergic system upon toxin-induced neuroinflammation

Authors: *M. PAPATHANOU[1,2], T. PERLMANN[1,2]
[1]Ludwig Inst. For Cancer Res., Stockholm, Sweden; [2]Cell. Mol. Biol., Karolinska Institutet, Stockholm, Sweden

Abstract: Developmental transcription factors (TF) are involved in the specification and differentiation of neurones. *Nurr1* is one such TF that has been extensively investigated for its role in the development of midbrain dopaminergic (DA) neurones. *Nurr1* knockout in mice leads

to lack of DA neurones and perinatal lethality. Work in our lab demonstrated that *Nurr1* is also crucial for the maintenance of fully functional adult DA neurones, which is in turn supported by the association of *Nurr1* gene variants with rare cases of sporadic and familial Parkinson's disease. However, the function of *Nurr1* in response to toxin insult remains elusive. Studies using *Nurr1* heterozygous mice have suggested a potential neuroprotective role of *Nurr1* against 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine or lactacystin neurotoxicity. It nonetheless remains uncertain whether the effects are due to *Nurr1* deficiency in mature neurons or if they are a consequence of developmental abnormalities. Moreover, lentiviral short hairpin RNA knockdown of *Nurr1* has suggested a role in DA neuroprotection against lipopolysaccharide-induced neuroinflammation by an anti-inflammatory activity within reactive microglia. Yet, it is unclear if *Nurr1* expression within neurons is also important for protection against inflammation-induced neurodegeneration. The aim of this study was to thus investigate inflammation-induced neurotoxicity in *Nurr1* conditional knockout mice.
Nurr1 floxed (C57/Bl6) mice were crossed with the tamoxifen-inducible Cre recombinase transgenic line under the dopamine transporter promoter. Mice were treated with tamoxifen at 4 weeks, followed by intranigral injection of the polyinosine-polycytidylic acid or vehicle at 8-10 weeks of age. The brains were subsequently analysed by immunohistochemistry using dopaminergic, microglial, astrocytic, phagocytic and apoptotic markers.
Nurr1 ablation increased vulnerability in PolyI:C-induced neurotoxicity. There was a time-dependent reduction in DA striatal innervation and a dose-dependent axonal degeneration, accompanied by phagocytosis but without significant signs of apoptosis. Finally PolyI:C led to astrogliosis and microgliosis although the expression of the toll-like receptor was evident in neurones and microglia but not in astrocytes.
In conclusion these results suggest that *Nurr1* is continuously important for protection of adult DA neurons and also suggest that functions within neurons contribute to DA neuroprotection in response to inflammation. These studies may therefore be of relevance in the context of Parkinson's disease.

Title: The amygdala and bipolar disorder: A meta-analysis of volumetric change

Authors: P. RANE[1], C. HASELGROVE[1], S. HODGE[1], *J. F. BATES[2,3], J. A. FRAZIER[1], D. N. KENNEDY[1]
[1]Psychiaty, UMass Med. Sch., Worcester, MA; [2]Dept Psychiat, Harvard Med. Sch. Mass Gen Hosp, CHARLESTOWN, MA; [3]Psychiatry, Univ. of Massachusets Med. Sch., Worcester, MA

Abstract: The amygdala's involvement in the processing and expression of various emotions has captured attention of researchers for many years. Many studies involving amygdala changes in Bipolar disorder (BPD), a mood disorder, are published every year with seemingly inconsistent reports of volumetric findings. The amygdala is reported to be larger in the BPD patients compared to normal controls in many publications while other reports point towards smaller amygdala in BPD group. Comparisons between studies are confounded by a number of factors. Various methods of image acquisition, and volumetric analysis are employed. The studies also vary significantly in the age ranges, illness severity, illness duration, treatment status and comorbidities. This study was an effort to perform a meta-analysis on currently published reports to get an insight into any abnormalities in amygdala development in BPD patients.
The Internet Brain Volume Database (IBVD) offers a repository of volumetric data of different brain structures. IBVD was queried for amygdala volume reports in BPD and normal subjects. Publications were limited to those that had reports for both the groups as well as age ranges. The BPD group amygdala volume was converted to a singular z-score per BPD group by comparing it to corresponding control group from the same publication. These z-scores were plotted against the age average of the two groups.
The resulting plot points towards an interesting correlation where the young BPD groups (age <25) have negative z-scores while the older BPD groups (age >35) have positive z-scores. A few outliers that do not follow this pattern either have co-morbidities such as diagnosis of psychosis or ADHD. We hypothesize that this could be an age effect, however, it can also point towards an effect of disease and/or treatment durations. This is supported by the fact that most of the drug naïve BPD groups have smaller z-scores than the treated BPD groups, irrespective of the treatment.
This meta-analysis points towards the presence of a substantial age effect in the nature of the volumetric differences seen in the amygdala. This is impacted directly by effects such as age of illness onset, illness duration, medication status and duration, etc. As it is clear that all these factors play in important role in the meaning of any specific observation of amygdala volume, it highlights the importance of report of more standardized and detailed population characteristics by the authors. Detailed understanding of these additional effects will be necessary to elucidate the intriguing age relationship and direction reversal of amygdala volumetric observations relative to healthy subjects.

Title: Network-level differences in effective connectivity during affect labeling in bipolar disorder

Authors: *S. TORRISI, E. LAU, N. VIZUETA, C. A. PENFOLD, S. Y. BOOKHEIMER, L. L. ALTSHULER
UCLA, LOS ANGELES, CA

Abstract: Background:
Bipolar Disorder (BP) involves dysfunction of emotion regulation. Using Dynamic Causal Modeling (DCM) with fMRI, we examined differences in effective connectivity in a subset of regions comprising the (incidental) emotion regulation network, specifically evaluating the role of the posterior inferior frontal gyrus (Broca's Area, BA44/45) in the linguistic labeling of emotional faces.
Methods:
34 euthymic BP I subjects (average age: 41.6 ± 12 years, 19 male) and 42 age- and gender-matched control subjects (41.5 ± 12, 23 male) were tested with a well-validated affect labeling paradigm. Standard general linear model analysis of label affect in SPM8 revealed greater recruitment of right vlPFC (BA 47) in controls and greater recruitment of subgenual ACC in bipolar subjects. Regions demonstrating equivalent levels of activation in both groups, however, were chosen for DCM analysis. During labeling affect vs matching affect, all subjects together showed strong activations in anterior insula and Broca's area. Thus time series were extracted from each of five left hemisphere regions strongly activated by labeling emotional facial expressions (FFA, amygdala, anterior insula, vlPFC, and Broca's area). Our models tested within groups the causal involvement of Broca's area and its path of modulation to the amygdala during labeling. The model space was parsed into orthogonal families to test commonalities across model permutations, and Bayesian model averaging (BMA) was performed on winning families to determine parameter estimates and weights between regions.
Results:

Results of final model comparison revealed different winning models between groups, indicating that labeling negative emotional faces involves a different pattern of connections in BP than in controls. Family-level Bayesian Model Selection (BMS) and BMA also clarified the roles of cortical regions and their influence on the amygdala.

Conclusion:

These findings indicate that the network recruited during incidental emotion regulation differs between euthymic BP and controls, providing novel effective connectivity evidence for trait dysfunction of the disease.

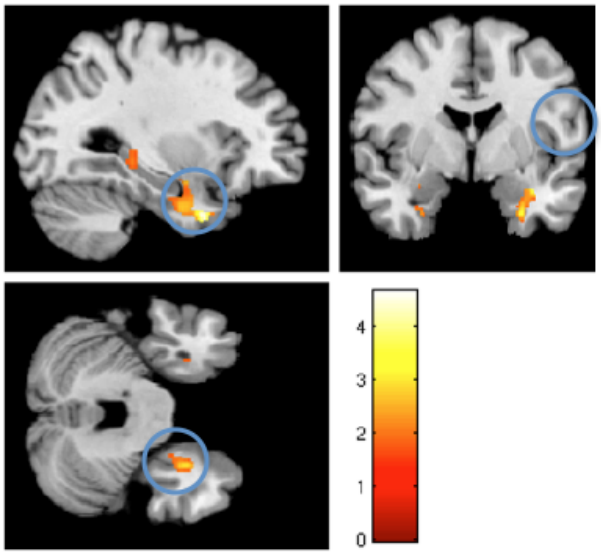
Title: Association between hippocampal grey matter volume and rates of associative learning rate in controls but not schizophrenia or bipolar patients

Authors: *B. B. YANOS[1,2], R. WHITE[3], M. BELLANI[4], G. RAMBALDELLI[5], P. BRAMBILLA[6], V. DIWADKAR[7]

[1]DMC Neurosci. and Psychology Dept., Brownstown, MI; [2]Psychiatry and Behavioral Neurosci., Wayne State Med. Sch., Detroit, MI; [3]Psychiatry and Behavioral Neurosci., Wayne State Med., Detroit, MI; [5]Dept. of Med. and Publ. Hlth., [4]Univ. of Verona, Verona, Italy; [6]Univ. of Udine, Udine, Italy; [7]Psychiatry and Behavioral Neurosci., Wayne State Univ. Med. Sch., Detroit, MI



Abstract: Background: The hippocampus is central in memory formation and reported as central to the pathophysiology of schizophrenia (SCZ) and bipolar disorder (BP; Brambilla et al., 2011). Tasks of learning and episodic memory are particularly relevant to the study of hippocampal pathophysiology (Diwadkar et al., 2008). Hippocampal volume has been generally associated with integrity of episodic memory (Rodrigue & Raz, 2004) though these relationships have never been investigated in patients with SCZ or BP. Here we use Voxel Based Morphometry (VBM) to assess the relationship between hippocampal grey matter volume and learning rate during an associative learning paradigm (Brambilla et al., 2011) in a group of age- and gender-matched healthy controls (HC), SCZ and BP.

Methods: Subjects participated in an object-location paired associative learning task (Diwadkar

et al., 2008) administered the same day that structural MRI data were collected. Learning rates from the task were derived based on fitting negatively accelerated learning curves (performance=1-e$^{-rate*time}$) to individual subject data. Data were obtained from 17 SCZ (7 F, mean age=36 yrs, sd=8.1; learning rate=0.17, sd=.1), 12 BP(8 F,mean age:41, sd=9.6;learning rate=0.34, sd=.4) and 22 HC (8 F, mean age=33 yrs, sd=7; learning rate=1.24, sd=.4). Subjects wereassessed using the Structured Clinical Interview for Axis I DSM-IV Disorders (SCID-I). Data were analyzed using DARTEL (SPM8; Ashburner, 2007), and group differences in hippocampal volume and regressions with learning rate were investigated in 2nd level analyses corrected for cluster extent (p< .05).

Results: As seen in the figure, only HC evinced significant positive correlations between learning rate and hippocampal volume.

Discussion: HC were characterized by systematic positive relationships between hippocampal structure and learning related function, though these correlations were absent in the patient groups. These negative results imply that SCZ and BP (relative to HC) may be characterized by dysfunctional hippocampal structure-function relationships.

Hippocampal clusters (in HC) with a positive relationship to learning rate are depicted (insets) in sagittal, coronal and axial views.

Title: Functional connectivity during facial-emotion recognition in euthymic bipolar disorder

Authors: *M. C. CHAMBERS, A. IRIMIA, L. ALTSHULER, J. VAN HORN
Lab. of Neuro Imaging (LONI), Univ. of California Los Angeles, Los Angeles, CA

Abstract: Bipolar disorder is characterized by periods of mania, depression and euthymia; the exact cause of the disorder has proved elusive. Even during euthymia, a wide variety of brain regions show significant differences controls; dependent functional task. Differences in activation level and size have been reported in bilateral striatum [3, 2], Middle Frontal Gyrus (MFG) [4], Inferior Frontal Gyrus (IFG) [3, 4, 2] cingulate [4], thalamus, insula, lingual gyri, left amygdala , intrapietal sulcus, all three temporal gyri, right parahippocamopal gyrus, and intraparietal sulcus [1, 3, 2]. MPRAGE and a face/emotion task were carried out on a Siemens Trio 3T scanner, (TR 2s), and segmented using Freesurfer. 21 euthymic subjects (9F, 12M) and 18 control (10F, 8M) were scanned while performing three face/emotion tasks as in Altshuler et al. [1, 2]. We calculated full brain voxel-voxel connectivity using Mutual Information (MI). Data were motion corrected and signals from the ventricles, unlabeled voxels, and white matter regressed out. The upper 90th percentile of connectivity within each pair of regions was then taken for regional connectivities. MI lower than 0.2 bits were
treated as unconnected. To correct for multiple comparisons (168 × 168 regions), $1.77 \times 10{-}6$ was considered significant. During the face/emotion task, euthymic subjects showed higher connectivity than controls between: 1) right
caudate - ipsalateral temporal plane of the superior temporal gyrus, 2) right caudate - ipsalateral heschl's Gyrus, 3) right transverse temporal sulcus - left Frontal Marginal gyrus/sulcus 4) right heschl's gyrus - right transverse frontopolar gyrus/sulcus, 5) left amdala - right anterior occipital sulcus, 6) right medial orbital sulcus - ipsalateral occipital pole, 7) left orbital sulcus - right middle temporal gyrus (MTG), 8) left orbital sulcus - bilateral transverse collateral sulcus. The connections that showed increases in euthymic patients verse controls are necessary portions of facial emotion processing and were active in controls as well. Supranormal connectivity during emotion recognition suggests euthymic patients experience tighter neural integration, and less inhibition during emotion recognition. In particular higher amygdala-visual, MTG-prefrontal and prefrontal-transverse sulcus pairing indicates a lack modulatory influcence during face/emotion processing.

Title: Auditory gamma oscillation and cortical volume deficits in schizophrenia

Authors: *Y. HIRANO[1,3], M. QUAN[2], N. ORIBE[2,3], M. A. NIZNIKIEWICZ[2], S. KANBA[3], R. W. MCCARLEY[2], K. M. SPENCER[1]
[1]Psychiatry, Harvard Med. Sch. / VA Boston Healthcare Syst., Boston, MA; [2]Psychiatry, Harvard Med. Sch. / VA Boston Healthcare Syst., Brockton, MA; [3]Neuropsychiatry, Grad. Sch. of Med. Sciences Kyushu Univ., Fukuoka, Japan

Abstract: Objective:
Recent studies suggest that abnormalities in the oscillatory activity of neural circuits may have a critical role in the pathophysiology of schizophrenia. Forty Hz auditory steady state response (ASSR) impairments have been reported and hypothesized to reflect these neural network abnormalities in chronic schizophrenia patients (SZ) and first episode psychosis compared to healthy controls (HC). However, the relationship between gamma oscillation deficits and

structural abnormalities of the auditory cortex in schizophrenia is not clear. Here we examined whether 40 Hz ASSR deficits in SZ are associated with volume reductions of Heschl's gyrus (HG), particularly in the left hemisphere, where both abnormalities have been associated with auditory hallucinations.
Methods:
Electroencephalogram was recorded from 24 SZ (4 females) and 24 HC (4 females) matched for demographic data. Stimuli were 20-, 30-, and 40-Hz binaural click trains. Time-frequency analyses (PLF: phase locking factor, EP: evoked power) were performed for each ASSR. MRI volumes were calculated for gray matter of HG. Clinical symptoms were assessed by PANSS.
Results:
ASSR PLF at 40 Hz and HG volume were significantly reduced in SZ specifically in the left hemisphere compared to HC. There were no significant differences in EP. Left lateralized 40Hz ASSR PLF reduction was correlated with total positive symptoms and hallucination symptoms. For the ASSR-HG associations, 40 Hz ASSR PLF was positively correlated with left HG volume in SZ.
Conclusions:
These findings support the presence of functional neural oscillatory deficits, which are correlated with underlying structural abnormalities and positive symptoms. We propose that assessing ASSR-PLF in SZ may provide a sensitive biomarker for the integrity of functional and structural neural networks that are fundamentally altered in SZ.

Title: Resting state functional connectivity in pediatric bipolar disorder

Authors: *A. A. LISO NAVARRO, E. M. SIKOGLU, D. KENNEDY, J. A. KING, J. A. FRAZIER, C. M. MOORE
Psychiatry, UMASS Med. Sch., Worcester, MA

Abstract: Bipolar disorder is a lifetime condition with a prevalence of 1%, and in the recent years it has been recognized that this disorder may present as early as childhood and adolescence. Children and adolescents with Pediatric Bipolar Disorder (PBD) may first exhibit cognitive impairments affecting domains such as attention and executive functions.
Non-invasive techniques such as functional Magnetic Resonance Imaging (fMRI) may allow us to further understand the mechanisms underling the pathophysiology of PBD and its associated cognitive deficits. Some of the brain regions linked to the pathophysiology of PBD include the Anterior Cingulate Cortex (ACC) and prefrontal cortex. In this work we studied resting state functional connectivity (rs-FC: a technique that allows one to assess spontaneous brain activity; using temporal correlations, one can examine the functional connections between a region of interest (ROI), namely seed region, and the rest of the brain) in a sample of children with PBD (n=7, mean age=12.14±2.67 years) and Typically Developing children (TD) (n=18, mean age=12.22±2.71 years).
Subjects were scanned on a 3T Philips System and an EPI sequence was performed (TE=30msec, TR=2500msec, slice thickness:3mm, 50 slices) Seed based rs-FC (seed at ACC MNI coordinates (0,44,10)). Analysis was carried using SPM-8 and DPARSFv2.0. The connectivity patterns for children with PBD and TD participants were compared through a two-sample t-test (corrected for False Discovery Rate, $p < 0.05$ considered significant).
There is more connectivity in the TD group than the PBD group, between the ACC base seed and left cortex orbitofrontal, right superior frontal gyrus and left medial temporal gyrus (FDR corrected $p<0.05$).
Importantly the orbitofrontal cortex, superior frontal gyrus (both part of the prefrontal cortex) and left medial temporal gyrus are implicated in different cognitive tasks, which are impaired in PBD. The decreased connectivity shown in PBD between the ACC and these areas could suggest a disruption in the brain “rewiring” in PBD, may be due to an asynchrony in brain maturation in PBD.

Title: ARC risk predicts PFC function, hippocampal activation, and PFC-hippocampal connectivity in an encoding and retrieval memory task

Authors: *A. B. ZHEUTLIN[1], J. H. CALLICOTT[1], W. D. YATES[1], M. G. WHITE[2], V. S. MATTAY[2,3], Q. CHEN[2,3], K. H. WANG[2], D. R. WEINBERGER[1,2,3]
[1]Unit on Dynamic Imaging Genetics, CBDB, GCAP, DIRP, NIMH, NIH, Bethesda, MD; [2]Genes, Cognition, and Psychosis Program, DIRP, NIMH, NIH, Bethesda, MD; [3]The Lieber Inst. for Brain Development, Johns Hopkins Med. Campus, Baltimore, MD

Abstract: Background: We have recently found evidence for an association between a single variant in ARC and risk for schizophrenia (Kirov et al., 2012). ARC is an activity-regulated immediate early gene thought to be important for activity-dependent neuronal specificity (Wang et al., 2006). Previously, we found risk at this variant was associated with primary deficits in PFC-hippocampal connectivity in an N-back working memory task (Zheutlin et al., 2012). Here, we investigated whether this variant of ARC predicts prefrontal and hippocampal activation, as well as altered coupling between these two regions, in a hippocampus-mediated task.
Methods: 187 healthy subjects completed a picture encoding and retrieval (PEAR) memory task and were scanned using GE EPI at 3T (Milwaukee, WI). ARC effects were assessed in SPM5 using ANCOVA with age, gender, and performance metrics included as nuisance variables. First level activation and PPI analyses included above were performed as described previously (Callicott et al., 1999; Rasetti et al., 2011). Connectivity was assessed with PPI analysis using a hippocampal seed.
Results: We found that genetic risk at this SNP was correlated with increased activation in the DLPFC and hippocampus in the PEAR encoding & retrieval episodic memory task. Additionally, increased risk was correlated with increased coupling between the prefrontal cortex and the hippocampus.
Conclusions: In healthy subjects, ARC risk predicted abnormal PFC function, hippocampal activation, and PFC-hippocampal connectivity in a hippocampus-mediated memory task.

Title: Effects of ketamine on gamma-band oscillations in MEG-data: A comparison with chronic schizophrenia

Authors: D. RIVOLTA[1], A. SAUER[1], T. HEIDEGGER[2], K. BIRKNER[1], B. SCHELLER[2], *L. MELLONI[1], M. WIBRAL[2], W. SINGER[1], P. J. UHLHAAS[1]
[1]Neurophysiol., Max Planck Inst. For Brain Res., Frankfurt Am Main, Germany; [2]Goethe-University, Frankfurt Am Main, Germany

Abstract: There is evidence to suggest that the pathophysiology of schizophrenia involves hypofunctioning of the N-methyl-D-aspartate (NMDA) receptor. To test the validity of this model, we measured neural oscillations in the 30 -120 Hz range with Magnetoencephalography (MEG) during the administration of a sub-anesthetic dose of ketamine, a non-competitive antagonist at the NMDA-Receptor site in healthy controls. Furthermore, MEG-data was also obtained from patients with chronic schizophrenia and matched controls.
10 normal participants were administered ketamine (0.006 mg/Kg) or a placebo saline solution in a within-subject design. In addition, 16 controls and 16 chronic patients with schizophrenia were assessed. A moving sinusoidal grating (5° of visual angle) was presented and the task for participants was to detect the acceleration of the grating through a button press. MEG-activity was recorded with a 275-channel CTF MEG system. Structural brain images (MRIs) were collected and a beamforming technique was adopted to localize the source of oscillations.
In healthy controls, ketamine led to a reduction in induced gamma band oscillations (45-75 Hz) over occipital sensors, which was localized to early visual areas (V1/V2). This reduction in high-frequency oscillations during visual stimulation is comparable to the pattern of impairments in chronic patients with schizophrenia. Thus, our data support the view that gamma-band oscillations and associated cognitive deficits may involve the hypofunctioning of NMDA-receptors, suggesting a crucial role of aberrant glutamatergic neurotransmission in the pathophysiology of schizophrenia.

Title: Effective connectivity deficits in numerical set pattern evaluation and updating in schizophrenia

Authors: *C. M. KAPLAN[1], J. L. MOLINA[1], Q. CHEN[1], J. A. APUD[1], D. R. WEINBERGER[1,2], H. Y. TAN[1]
[1]NIMH, Bethesda, MD; [2]Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Introduction:
Inferring and abstracting logical patterns from information in the environment is impaired in psychotic disorders. It has been shown prefrontal cortex may be implicated in failure of these higher cognitive operations; striatal and hippocampal regions have also been implicated in failure to update and learn from information gathered. However, less is known about their integrated function in larger brain networks, such as how bilateral parietal, premotor, and sub-regions in prefrontal cortex interact with the subcortical regions in these operations, and which circuits are impaired or compensatory in psychosis.
Methods:
24 normal controls (NC) and 14 schizophrenia patients (SZ) performed an event-related fMRI task in a 3T-scanner. Participants were presented with numbers varying stochastically about an underlying base integer (number set). The sets of numbers also shifted stochastically up or down by one unit at the base integer. Subjects were to respond when they inferred the number set has shifted, and to update their representation of the new base integer. Imaging data was analyzed using SPM8. Dynamic Causal Models were estimated at subject level within ROI masks based on combined NC+SZ group-level peaks.
Results:
SZ performed with larger total prediction error ($p=0.0044$) and larger mean prediction error at response ($p=0.0075$). At set-updating, task modulated effective connectivity was reduced in SZ ($p<0.05$) at bilateral anterior (APFC), dorsolateral prefrontal (DLPFC), premotor (PMd), parietal (PAR), striatal (STR) and hippocampal (HIP) regions. Task-critical networks in NC that correlated with overall performance and were impaired in SZ included left to right connectivity at APFC and at DLPFC, and left prefrontal regions to STR and PAR connectivity. However, in

SZ there was negative correlation, leading to better prediction performance of number set shifting, from engagement of left hemisphere rostral to caudal effective connectivity (DLPFC to APFC and from APFC to STR, HIP, and PAR).
Discussion:
Effective numerical set evaluation and updating engaged bilateral rostral to caudal patterns of frontal-parietal-striatal-hippocampal effective connectivity, which was dysfunctional in SZ. However, increased left rostral to caudal effective connectivity, particularly in networks engaging APFC, was associated with improved performance in SZ and may be compensatory. The effects of medication in these findings remain to be explored.

Title: Resting state functional connectivity of brain reward circuitry in patients with schizophrenia and cannabis use disorder: Effects of cannabis and dronabinol

Authors: *A. S. FISCHER[1], S. WHITFIELD-GABRIELI[2], R. M. ROTH[1], A. I. GREEN[1]
[1]Psychiatry, Geisel Sch. of Med. At Dartmouth, Lebanon, NH; [2]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Background:
Cannabis use disorder (CUD), present in over 40% of patients with schizophrenia (SCZ), worsens disease progression. Unfortunately, available treatments for SCZ are rarely successful in limiting cannabis use. Development of effective treatments for these patients will be facilitated by a more complete understanding of the basis of their cannabis use. We have proposed that patients with SCZ and CUD use cannabis to ameliorate abnormalities present within their brain reward circuit (BRC). In the present study, we used resting state functional connectivity (RSC) to assess the intrinsic functional architecture of the BRC. We then investigated the effects of cannabis and dronabinol (synthetic delta-9-tetrahydrocannabinol [THC]) on RSC of reward circuitry in these patients.
Methods:

Participants included 10 patients with SCZ and CUD and 6 healthy controls. Patients abstained from cannabis and other substance use for a minimum of seven days prior to scanning. Subjects completed an eight minute fMRI resting scan at baseline and again after either smoking a 3.6% THC cannabis cigarette and ingesting a placebo pill (n=5) or smoking a placebo cigarette and taking an active 15mg dronabinol pill (n=5). Connectivity was analyzed using a region of interest (ROI)-to-ROI analysis between bilateral nucleus accumbens (Nac) source ROIs (anatomically defined 4mm spheres surrounding peak Nac coordinates), 88 broadmanns regions, and 5 anatomically defined BRC ROIs. Between group connectivity differences were assessed using ANOVA. Group x Time interactions were determined with repeated measures ANOVA.

Results:

Measurements at baseline revealed decreased RSC between bilateral NAC ROIs and other key BRC regions (ventral tegmental area, amygdala, hippocampus, caudate, putamen, medial prefrontal, orbitofrontal, and anterior cingulate cortices) in patients with SCZ and CUD as compared to controls ($p<0.05$, uncorrected). Moreover, smoked cannabis and oral dronabinol each increased connectivity within the BRC ($p<0.05$, uncorrected).

Conclusion:

The data from this small study sample suggest that BRC connectivity is reduced in patients with SCZ and CUD, and that cannabis and dronabinol may move the connectivity toward that seen in normal subjects. Our findings support the use of RSC as a neuroimaging 'biomarker' to identify BRC abnormalities present in patients with SCZ and CUD and, potentially, to track the effect of pharmacologic agents on this circuitry. Moreover, if these findings are confirmed in a larger sample, they may suggest that dronabinol should be studied as an adjunctive treatment (with antipsychotic medications) to help reduce cannabis use in SCZ.

Title: Reduced n-acetylaspartate in the frontal cortex and ventral hippocampus following sub-chronic phencyclidine treatment in the female rat.

Authors: S. MARSH, S. L. MCLEAN, J. C. NEILL, *M. K. HARTE
Pharmacol., Univ. of Bradford, Bradford, United Kingdom

Abstract: Schizophrenia is a chronic psychiatric disorder characterised by positive, negative and cognitive symptoms. Although the exact cause remains elusive there is substantial evidence for neuronal dysfunction in the brains in patients with the disorder. N-acetylaspartate (NAA) is present in high concentrations in the CNS and is considered to be a general marker of neuronal loss and/or cellular dysfunction. Numerous magnetic resonance studies have shown reductions in levels of NAA in schizophrenia, with deficits correlated to disease severity. Studies have also demonstrated recovery of NAA levels following acute brain injury. Further studies have also reported increases in NAA following pharmacological therapy. Taken together these studies demonstrate its potential use as a biomarker for assessing restoration of neuronal function following successful treatments. We have consistently demonstrated that sub-chronic phencyclidine (PCP) treatment in the female rat produces robust cognitive deficits and pathological changes that mimic those reported in schizophrenia. The aim of this study was to investigate levels of NAA in the brain in the female rat following our sub-chronic PCP treatment regime.

Adult female (n=16) hooded lister rats received sub-chronic PCP (2 mg/kg bi-daily, i.p, n=8) or vehicle (saline 0.9% bi-daily, i.p, n=8) for 7 days followed by a 7 day washout period. Six weeks later the rats were killed and brains removed. Brains regions were dissected in relation to Bregma coordinates [Frontal Cortex, +4.7 to +3.2mm; Striatum, +1.7 to -0.2mm; Dorsal Hippocampus -3.3 to -4.8mm; Ventral Hippocampus -4.8 to -6.3mm; Temporal Cortex -3.3 to -4.8mm mm. Tissue was homogenised, samples prepared and extracted with ISOLUTE SAX anion exchange columns, followed by HPLC analysis using UV detection. Compared to vehicle, sub-chronic PCP treatment produced significant reductions in NAA, in the frontal cortex ($p<0.05$) and ventral hippocampus ($p<0.05$), with no significant changes in the striatum, dorsal hippocampus or temporal cortex. These preliminary findings demonstrate that sub-chronic PCP administration causes reductions in NAA in the frontal cortex and ventral hippocampus. This provides further evidence to suggest that sub-chronic PCP can mimic aspects of the neuronal pathology of schizophrenia and may provide a translational biomarker for assessing the effect of treatment on indicators of normal neuronal function. The relationship of the reductions in NAA in these regions to the cognitive deficits reported in the sub-chronic PCP model remains to be determined.

Title: Abnormal white matter dti connectivity in children and adolescents with a first degree relative for schizophrenia.

Authors: *M. WEBER, S. HART, C. BELLION, S. RAMSEY, J. BIZZELL, A. BELGER
Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Background: Schizophrenia has most recently been characterized as a neurodevelopmental disorder associated with aberrant maturation of cortical connectivity. Whether aberrant connectivity precedes onset of psychosis and is present in at-risk children is unclear. The goal of the present study was to examine white matter connectivity in fronto-limbic and fronto-striate tracts and regions in familial high-risk children and adolescents.
Methods: DTI images were acquired on 23 children ages 9-18 with a first degree family member with schizophrenia (FHR) and 38 age-, gender, and ethnicity matched controls (CTLs). Acquisition consisted of two 15-direction (+ one baseline) 2mm isotropic full-brain EPI DWI acquisitions.Following DTI QA analysis and artifact removal, the diffusion tensors and diffusivity measures (FA, MD, GA, AD and RD) were calculated. Two analysis methods were implemented, one examining Regional Diffusion Statistics, and the second focusing on Fiber-Tract based statistics. For the ROI-based analysis, T1 and T2-weighted images for each subject were run through automatic tissue segmentation (itkEMS), and automatic cortical and sub-cortical parcellation tools. Regional diffusion statistics were calculated for each of the cortical and sub-cortical white-matter masked ROIs. For the tract-based analysis, subjects' FA maps were warped using a non-linear registration technique (AtlasWerks) to create an atlas for the study population. The resulting dataset of fiber tracts were run through FADTTS to measure the variability of diffusivity statistics along the fibers and their association with diagnosis and age as covariates.
Results: ROI-based analyses revealed significantly larger FA ($p<.02$) in prefrontal and cingulum regions in HR compared to CTL children. Preliminary fiber-tract analysis results revealed significant group and age effects on left and right cingulum pathways, consistent with the ROI analysis.
Summary: Our findings show that white matter organization along fronto-limbic regions is aberrant in children with familial risk for schizophrenia.

Title: Structural and functional working memory deficits associated with adolescent-onset psychosis

Authors: *A. SCHVARCZ[1], K. H. KARLSGODT[2], P. BACHMAN[2,3], M. JALBRZIKOWSKI[1], T. G. VAN ERP[4], T. D. CANNON[1,2,3], C. E. BEARDEN[1,2,3]
[1]UCLA Dept. of Psychology, Los Angeles, CA; [2]Dept. of Psychiatry and Biobehavioral Sci., [3]Semel Inst. for Neurosci. and Human Behavior, UCLA, Los Angeles, CA; [4]Dept. of Psychiatry & Human Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Background: Adolescent-onset psychosis (AOP) is typically associated with more severe deficits in working memory and attention relative to the adult-onset form of illness. Given the relationship between cognitive abilities and the well-documented gray and white matter abnormalities that occur in schizophrenia, as well as the neuroanatomical changes that occur throughout adolescence, studies have just recently begun to investigate the correlation between structural changes and corresponding physiological and behavioral outputs in AOP. This study seeks to better understand how variability in structural brain connectivity constrains functional-physiological connectivity and capacity in individuals with AOP relative to healthy controls. Methods: Functional magnetic resonance imaging (fMRI) scans were obtained from AOP patients (N=16) and healthy comparison subjects (N=16) matched for age (range: 12-22), gender,

IQ, ethnicity, self and parent education, and handedness. Diffusion tensor imaging (DTI) scans were obtained from a subset of those participants (patient N=9, control N=13). While in the scanner, subjects performed a spatial capacity task manipulating working memory load in which 1, 3, 5, or 7 dots are shown per trial, with subjects asked to identify if a probe dot's location corresponded to a location of one of the target dots (12 trials per load). fMRI data were analyzed with FSL FEAT; DTI data were analyzed with Tract-Based Spatial Statistics. Threshold for cluster statistical significance was set at $Z>2.3$; $p<0.05$.
Results: fMRI analyses revealed a distinct pattern of age-associated changes in neural activity during task performance in AOP patients relative to controls in multiple brain regions. Under greater working memory demand, controls demonstrated greater neural activity as compared to patients in posterior brain regions. Of the working memory tracts examined in DTI analyses (inferior longitudinal fasciculus (ILF), superior longitudinal fasciculus (SLF), and cingulate gyrus), a significant positive association between age and fractional anisotropy (FA) was observed bilaterally in the ILF in controls, which was not observed in the AOP group. This suggests the possibility that patients fail to show expected age-associated increases in FA in working memory circuitry.
Discussion: This study provides additional clarity into brain structure-function relationships in AOP as they relate to working memory dysfunction. Future studies will employ more advanced joint modeling approaches such as joint independent component analysis to further assess these relationships and better elucidate endophenotypes of schizophrenia.

Title: Increased prefrontal-parietal effective connectivity at number processing in working memory in schizophrenia

Authors: *J. MOLINA[1], C. M. KAPLAN[2], Q. CHEN[2,3], J. A. APUD[2], D. R. WEINBERGER[2,3], H. TAN[2]

[1]NIH, Washington, DC; [2]Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Leiber Inst. for Brain Develop., Baltimore, MD

Abstract: Introduction:
Symbolic number processing engages parietal cortex, especially inferior parietal sulcus, and is a uniquely human ability. Working memory (WM) engages prefrontal-parietal cortices and is a limited capacity system that supports the brief storage and temporal integration of information. WM but not number processing is known to be dysfunctional in schizophrenia (SZ). However, less is known of how these brain processes may influence each other in SZ. Here, we examined, in healthy volunteers (HV) and SZ, effective connectivity of cortical networks during dissociable encoding of number symbols in WM, and subsequent processing of their relative numerosity.
Methods:
22 healthy volunteers (HV) without previous history of psychiatric or neurological disorders and 15 patients were processed in SPM8 and DCM10. Subjects were matched for performance, response time, age, and sex. Regions activated during WM conditions (Visual Cortex, VC; Dorsolateral Prefrontal Cortex, DLPFC; Ventrolateral Prefrontal Cortex, VLPFC; and Parietal Cortex, IPS) were selected for effective connectivity analyses.
Results:
During WM encoding, greater connectivity ($p<0.05$) was observed in forward VC→VL and backward VL→VC, DL→VC, VL→PC in SZ relative to HV. At numerosity comparison, there was greater connectivity from VC→PC in SZ. Moreover, SZ engaged sustained frontal-parietal network connectivity during numerosity comparison, whereas HVs performed equivalently with local parietal cortex processing and less cortical network connectivity ($p<0.05$).
Conclusion:
SZ patients engaged increased cortical network effective connectivity during WM encoding without performance advantage. The increased network coherence appeared sustained at numerosity comparison in SZ whereas HV engaged local parietal processing. The abnormal increased network coherence during WM encoding may reflect dysfunction in SZ that sets the stage for impairments in subsequent processing. Medication status, however, could be a confounder.

Title: Just not yet: Earlier age of marijuana use predicts poorer neurocognitive performance and alterations in brain structure

Authors: *S. A. GRUBER[1], M. DAHLGREN[2], K. A. SAGAR[2], A. GONENC[1], S. E. LUKAS[1]
[1]McLean Hospital/Harvard Med. Sch., BELMONT, MA; [2]Cognitive and Clin. Neuroimaging Core, McLean Imaging Ctr., Belmont, MA

Abstract: Marijuana (MJ) remains the most popular illicit drug in the US. While studies have reported that chronic MJ use is related to cognitive impairments, the perceived risk of MJ use has declined, which has been accompanied by an increase in rates of use, especially among younger adults. Diffusion tensor imaging (DTI) provides a quantitative measure of white matter microstructure, also reported to be altered in MJ smokers. In order to assess the impact of age of onset of MJ use on cognitive performance and white matter microstructure, we analyzed data from 46 chronic MJ-smokers and 31 non-MJ smoking control subjects who completed a neurocognitive battery and DTI scanning.

Overall, MJ smokers exhibited significantly worse performance on tasks of executive function, including the Wisconsin Card Sorting Test (WCST), Stroop Color Word Test, and the Trail Making Test (TMT), and significantly higher levels of impulsivity, measured by the Barratt Impulsiveness Scale (BIS) compared to control subjects. DTI analyses revealed MJ smokers also had significantly lower levels of fractional anisotropy (FA), a measure of directionality and coherence in white matter fibers, and higher levels of mean diffusivity (MD) in the left and right genu of the corpus callosum relative to controls. To clarify the impact of age of MJ onset, MJ smokers were separated into those who began smoking prior to age 16 (early onset; n=23) and those who began using MJ at age 16 or older (late onset; n=23). Interestingly, analyses revealed that the cognitive, impulsivity and white matter differences detected between the MJ smokers and control subjects were primarily driven by the early onset MJ group.

Within the MJ smokers, regression analyses revealed that earlier age of MJ onset was predictive of poorer performance and altered white matter. Earlier MJ onset predicted lower FA in the left and right genu (β= .344, p=.09; β= .358, p=.08) and higher MD in the right genu (β=-.345, p=.09), and predicted both longer time required to complete Part A (β= .304, p=.05) and increased errors on Part B (β=-.302, p=.05) of the TMT. Earlier MJ onset also predicted both higher frequency (β=-.346, p=.01) and magnitude of MJ use (β=-.375, p=.01), measured as smokes per week and grams per week. Taken together, data suggest that early MJ use results in poorer cognitive function, higher impulsivity and altered brain structure relative to non-MJ smokers. These findings underscore the importance of early identification and prevention of early, regular MJ use, as exposure to MJ during a period of developmental vulnerability appears to result in neurophysiological changes, which may have long-term implications.

Title: Differential consequences of repeated administration of a cannabinoid receptor agonist on limbic neuronal morphology in adolescent compared to adult rats.

Authors: *A. F. CARVALHO[1], B. A. S. REYES[3], N. SOUSA[2], E. E. J. VAN BOCKSTAELE[3]
[1]Neurosurg., [2]ICVS/3B's - PT Government Associate Lab., Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal; [3]Neurosciences, Thomas Jefferson Univ., Philadelphia, PA

Abstract: Cannabinoid receptor agonists are known to alter mood, cognition and perception. Several lines of evidence indicate that the impact of cannabinoid-based drugs is different in adolescence compared to adulthood. For example, cannabinoid-induced cognitive impairment is more evident during adolescence when compared to adulthood. In addition, adolescents report fewer episodes of aversion to cannabinoid-based drugs in comparison to adults, a finding that could contribute to the higher incidence of cannabis use during adolescence. In the present study, we used three-dimensional analysis of Golgi-stained neurons in the nucleus accumbens (Acb) of adolescent and adult rats that had been chronically treated with a synthetic cannabinoid receptor agonist, WIN 55,212-2 or vehicle. Results showed that exposure to WIN 55,212-2 significantly decreased dendritic length, dendritic branching and spine density in adult animals compared to age-matched controls. Interestingly, WIN 55,212-2 treatment only affected spine density in adolescent-treated animals when compared to control. These findings indicate a differential consequence to the effects of cannabinoids on neuronal morphology during the period of adolescence in a critical brain region involved in motivated behaviors. These morphological differences may contribute to the differential effects of cannabinoid-based agents on behavior in adult compared to adolescent animals.

Title: Molecular targets of cannabis action in the developing nervous system

Authors: G. TORTORIELLO[1], C. MORRIS[2], C. H. BOTTING[3], Y. L. HURD[2], *T. HARKANY[1,4]
[1]Karolinska Inst., Stockholm, Sweden; [2]Mount Sinai Sch. of Med., New York, NY; [3]Univ. of St Andrews, St Andrews, United Kingdom; [4]Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: Cannabis abuse during pregnancy is a leading socioeconomic problem since it imposes life-long modifications to the behaviors and cognition of affected offspring. Recent studies suggest that Δ^9-tetrahydrocannabinol (THC), the major psychoactive component from cannabis, can disrupt the spatial and temporal organization and efficacy of endocannabinoid signalling at CB1 cannabinoid receptors (CB_1Rs) in developing cortical neurons. Axonal growth may be particularly sensitive to THC action since CB_1Rs and the enzymes metabolizing endocannabinoids preferentially accumulate in the growth cones of cortical neurons, affecting growth cone steering decisions. We hypothesized that cannabis smoking during pregnancy can permanently change the cytoarchitecture, synaptic connectivity and functions of fetal forebrain neurons by erroneous recruitment of signaling networks to CB_1Rs in immature axons. We find that maternal cannabis exposure during pregnancy introduces axon fasciculation errors leading to the mistargeting of excitatory synapses and permanently impaired endocannabinoid-dependent and -independent forms of synaptic plasticity in the hippocampus of adult offspring exposed to THC *in utero*. Pharmacological dissection revealed that THC acts as a partial CB_1R agonist in the fetal brain, and recapitulates the bulk of the molecular modifications associated with WIN55,212-induced impairments of cortical development. We used global protein profiling to identify a 37-member hierarchical protein network downstream from CB_1Rs that confers cannabis sensitivity to developing cortical neurons by decreasing the rate and randomizing the subcellular foci of microtubule polymerization. We find that maternal THC exposure impacts the expression of select members of this protein network in the fetal human forebrain at mid-gestation, reinforcing our notion that THC perturbs the developmental dynamics of a signalosome domain required to maintain ordered axonal growth and guidance during the formation of cortical connectivity maps.

Title: High serum glutamate level is associated with positive response to acamprosate treatment.

Authors: *D.-S. CHOI[1], H. NAM[1], V. M. KARPYAK[3], X. LI[2], D. L. WALKER[1], D. J. HINTON[1], H. CHOI[1], O. ABULSEOUD[2], M. A. FRYE[2], D. A. MRAZEK[2]

Abstract: Acamprosate treatment is most effective in the maintenance of abstinence from alcohol. However, the efficacy of acamprosate is not uniform in all patients. Therefore, serum biomarkers associate with acamprosate efficacy would be useful for the identification of potential responders and develop an individualized treatment approach for alcohol dependence. We used LC-MS/MS to quantify serum metabolites and acamprosate levels in 90 alcohol dependent subjects (DSM-IV-TR) completing a 3-month trial of acamprosate treatment. We compared acamprosate levels and metabolite profiles between 44 responders (no alcohol consumption) and 46 non-responders (any alcohol consumption). Glutamate levels were significantly higher at baseline in the responder group compared to the non-responder group. Following acamprosate treatment serum glutamate levels in the responder group decreased significantly compared to baseline. Consistently, levels of glutamate related metabolites in the urea cycle also showed similar changes and were negatively correlated with glutamine levels. There was no change in glutamate or other metabolite levels in the non-responder group when comparing baseline levels to that following acamprosate treatment. Our data demonstrated that responders to acamprosate treatment have elevated serum glutamate levels, which are decreased by acamprosate treatment.

Title: Genetic models provide evidence for MPDZ involvement in sedative withdrawal and self-administration

Authors: *K. J. BUCK[1,2], L. C. MILNER[2], O. KOLOTUSHKINA[2], N. H. KOMIYAMA[3], D. ROSSI[2], S. GRANT[3]
[1]VAMC, PORTLAND, ; [2]Oregon Hlth. & Sci. Univ., Portland, OR; [3]Wellcome Trust Sanger Inst., Cambridge, United Kingdom

Abstract: Using robust behavioral models, positional cloning, expression and sequence analyses, we implicated *Mpdz* as a gene involved in ethanol and barbiturate withdrawal (*Nat Neurosci* 7:699, 2004), but *in vivo* evidence supporting its role in withdrawal behavior has been lacking. *Mpdz* codes for the multi-PDZ domain protein (MPDZ). Here, to assess its role *in vivo*, we report the development of transgenic mice with increased *Mpdz* expression (MPDZ-TG). Injection of an artificial bacterial artificial chromosome (BAC) construct (with *Mpdz* but no other full genes) into embryos resulted in transgenic founders from which we completed MPDZ-TG mice (DBA/2 background). We also developed an MPDZ knockout (heterozygote) model (MPDZ-KO; C57BL/6 background) using an embryonic stem cell line with an insertional

mutation in *Mpdz*, which we compared to wildtype (WT) littermates. Ethanol and pentobarbital (PB) withdrawal associated CNS hyperexcitability were assessed using the handling-induced convulsion. MPDZ-TG show less severe ethanol withdrawal than WT ($p<0.05$), with a trend for PB withdrawal ($p<0.1$). MPDZ-KO show more severe ethanol withdrawal than WT ($p<0.05$), and a trend for PB withdrawal ($p\sim0.1$). The strengths of the TG approach complement the limitations of the KO approach, and vice versa, so the finding that both support a role for MPDZ in sedative withdrawal is compelling. Additionally, self-administration analyses using a two-bottle choice paradigm indicate a main effect of genotype ($p<0.01$), with MPDZ-KO consuming more ethanol than WT. Ongoing analyses are comparing MPDZ-KO and WT to assess the potential impact of MPDZ expression on 5-HT_{2C} and $GABA_B$ receptor function. MPDZ physically associates with 5-HT_{2C} and $GABA_B$ receptors, and the substantia nigra pars reticulata (SNr) is implicated in mediating the effects of this QTL on withdrawal (*J Neurosci* 28:9840, 2008; *Behav Brain Res* 218:152, 2010) so we have initially examples voltage-clamped (V_h= -50 mV) SNr neurons. 5-HT (10 and 100 uM) induced inward currents in approximately 80 and 40% of MPDZ-KO and WT neurons, respectively; these currents are mediated by 5-HT_{2C} receptors in GABAergic neurons. MPDZ-KO also show a trend ($p<0.1$) for more severe convulsions in response to a 5-HT_{2C} receptor antagonist (SB242084, 10 mg/kg) compared to WT. The majority of SNr neurons had outward currents in response to a $GABA_B$ receptor agonist, with MPDZ-KO having greater response to 3 and 30 uM baclofen than WT ($p<0.001$). Our results suggest a relationship between reduced MPDZ expression and increased 5-HT_{2C} and $GABA_B$ receptor function.

Title: Pharmacological determinants of abuse-related morphine effects in an assay of intracranial self-stimulation in rats

Authors: *L. L. MILLER, S. S. NEGUS
Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Intracranial self-stimulation (ICSS) is a class of behavioral procedures that can be used to evaluate the abuse liability of drugs. Mu opioid agonist effects on ICSS reflect integration of both (a) rate-increasing effects that are associated with abuse liability, and (b) rate-decreasing effects that may limit abuse liability. This study investigated pharmacological determinants of the rate-increasing and rate-decreasing effects of morphine on ICSS. Male Sprague Dawley rats were equipped with electrodes targeting the medial forebrain bundle and trained to respond for stimulation under a fixed-ratio 1 schedule. Reinforcement rates were evaluated across a range of stimulation frequencies (56-158 Hz), and effects of morphine (cumulative doses of 0.32-10 mg/kg) on frequency-rate ICSS curves were determined. In drug naïve rats, significant but modest rate-increasing effects predominated at low morphine doses, but rate-decreasing effects emerged and predominated at higher morphine doses. Morphine effects were redetermined under two sets of conditions. The first experiment examined effects of morphine treatment history on morphine-induced changes in ICSS. Four groups of rats were exposed to protocols designed to establish graded histories of morphine exposure with or without the concomitant opportunity to engage in ICSS. In general, prior morphine exposure attenuated the rate-decreasing effects and enhanced the rate-increasing effects of morphine, and this effect of morphine exposure was greatest when morphine was administered daily prior to ICSS sessions. One neurobiological effect of morphine exposure is to decrease the density of functional mu opioid receptors in brain. Accordingly, the second experiment evaluated the degree to which effects of morphine exposure could be recapitulated by 24 hr pretreatment with the irreversible mu antagonist beta-funaltrexamine (ß-FNA; 0.32-3.2 mg/kg). The hypothesis predicted that opioid-induced rate-decreasing effects would be more sensitive than rate-increasing effects to pretreatment with ß-FNA; however, ß-FNA was not more potent to block morphine rate-decreasing effects. These results are consistent with earlier data to suggest that rate-increasing and rate-decreasing effects are mediated by anatomically distinct populations of mu receptors with similar sensitivities to ß-FNA but different sensitivities to morphine exposure. These data also suggest that a history of opioid agonist exposure may produce pharmacological and behavioral tolerance to morphine effects that limit abuse potential and enhance expression of morphine effects associated with abuse.

Abstract: Benzodiazepines are widely prescribed but their utility is limited by unwanted side effects, such as abuse potential. The mechanisms underlying the abuse-related effects of benzodiazepines are not well understood, although α1-containing $GABA_A$ receptors are thought to play a critical role. Furthermore, previous drug history has been shown to be a major determinant of the abuse-related effects of benzodiazepine-type drugs. In the present study, we examined the reinforcing effects of several α1-sparing compounds that vary with respect to intrinsic efficacy (determined by patch-clamp electrophysiology in cloned receptors) at α2, α3, and α5 subunit-containing $GABA_A$ receptors: MRK-623 (functional selectivity for α2/α3-containing receptors), TPA023B (functional selectivity for α2/α3/α5-containing receptors), and TP003 (functional selectivity for α3-containing receptors). The reinforcing effects of these α1-sparing compounds were compared with those of the non-selective partial agonist MRK-696, and non-selective full agonists, midazolam and lorazepam. Comparison of relative reinforcing effectiveness was determined in rhesus monkeys trained to self-administer either a benzodiazepine (midazolam) or a stimulant (cocaine), under a progressive ratio schedule of i.v. drug injection. Lacking efficacy at α1-containing receptors resulted in lower break points than the reference benzodiazepines. Moreover, the α1-sparing compounds were self-administered in midazolam-trained, but not cocaine-trained monkeys. Notably, the α3-selective compound TP003 had significant reinforcing effects, albeit with less reinforcing effectiveness relative to reference benzodiazepines. These results suggest α3-containing $GABA_A$ receptors may be important for the reinforcing effects of benzodiazepines in midazolam-trained monkeys, whereas α1-containing $GABA_A$ receptors may be crucial for the reinforcing effects of benzodiazepine-type compounds in animals with a history of stimulant self-administration.

Title: Differentiating neural networks with interleaved TMS-BOLD imaging: Insight into addiction

Authors: *C. A. HANLON[1], M. CANTERBERRY[2], J. J. TAYLOR[2], W. DEVRIES[2], M. S. GEORGE[2,3]
[1]Dept. of Psychiatry, [2]Med. Univ. of South Carolina, Charleston, SC; [3]Ralph S. Johnson VA Med. Ctr., Charleston, SC

Abstract: Introduction: Interleaved transcranial magnetic stimulation (TMS) and BOLD imaging in the MR environment provides us with a unique opportunity to probe neural circuitry. The purpose of the current study was to determine if, through the use of an optimized interleaved TMS-BOLD sequence in two cortical targets, we could differentially activate lateral and medial prefrontal cortex neural circuits.
Methods: Interleaved TMS/BOLD imaging data was acquired for 15 healthy individuals and 10 cocaine users who received TMS in 2 runs with the coil positioned over the: 1) dorsolateral prefrontal cortex (DLPFC, EEG: F3), and 2) orbitofrontal/medial prefrontal cortex (OFC/MPFC, EEG: FP1)(Magstim MR-compatible coil). The TMS pulse started 100ms before the onset of the next TR (9 second interpulse interval, 100% motor threshold). BOLD data was analyzed using standard parametric techniques. Additionally 5 participants were scanned twice to evaluate test-retest reliability.
Results: Among healthy controls, DLPFC TMS was associated with a significant elevation of BOLD signal in multiple dorsal cortical areas (middle frontal gyrus, middle temporal gyrus, superior frontal gyrus, brainstem, inferior parietal/angular gyrus, precuneus)**.** In contrast, OFC/MPFC TMS was associated with a significant elevation of BOLD signal in multiple medial and limbic subcortical areas (cingulate cortex, medial frontal gyrus, cuneus, caudate, middle temporal cortex, cerebellum ($p<0.05$, $k = 50$, corrected clusters). The cocaine users demonstrated

a similar pattern of activity, but has selective dysregulation in the OFC/MPFC network. **Conclusions:** These novel data demonstrate that it is possible to differentially activate known cortical-subcortical networks through an optimized TMS/BOLD sequence over the DLPFC and the OFC/MPFC. Test-retest reliability is high in healthy controls and among cocaine users there is a selective deficit in OFC/MPFC circuit function. These data have important implications for both basic neuroscience research and in patient populations that may have pathology differentially affecting mesolimbic versus mesocortical circuitry.

Title: The relationship between excessive ethanol drinking, level of intoxication, and plasma corticosterone across a bitonic function of fixed time intervals in ethanol-preferring and non-preferring mouse strains.

Authors: *M. M. FORD, A. D. MCCRAKEN, A. M. STEELE, K. A. GRANT
Dept Behavioral Neurosci, Oregon Hlth. & Sci. Univ., PORTLAND, OR

Abstract: Scheduled-induced polydipsia (SIP) employs intermittent schedules of food reinforcement to generate excessive drinking, and accumulating evidence suggests that drinking typographies established during induction in cynomolgus monkeys are predictive of future chronic heavy drinking. The current work sought to further explore the relationship between the amount/pattern of 5% v/v ethanol (5E) or water consumed, the level of intoxication achieved (via blood ethanol concentration; BEC) and the response of the hypothalamic-pituitary-adrenal axis (via plasma corticosterone; CORT) across a range of fixed time (FT) intervals of food delivery. Male mice (C57BL/6 and DBA/2; n = 6/strain/fluid) were food restricted to 90% free-feeding body weight and then serially exposed to FT schedules (0, 0.5, 1, 2, 3, 5, 7, 10, 20 and 60 min) during daily 60 min sessions. Both strains exhibited a bitonic function (ascending and descending limb) of 5E intake as the FT interval was progressively lengthened, with peak

intoxication occurring at FT-5 (2.1±0.2 mg/ml in C57BL/6 versus 1.0±0.4 mg/ml in DBA/2 mice). Plasma CORT levels were positively correlated with BEC during the ascending limb in C57BL/6 ($r = 0.87$; $P < 0.001$) and DBA/2 ($r = 0.48$; $P < 0.01$) mice, but not during the descending limb. This suggested that the CORT response was driven primarily by the induction schedule and not by ethanol consumption, as CORT levels remained elevated as 5E intakes declined during the descending limb and similar CORT concentrations were observed across FT intervals when water was the available solution. Clear strain differences in 5E lick distribution across the inter-pellet intervals (IPIs) and bout patterns were also apparent. C57BL/6 mice consumed 5E throughout the entire IPI whereas DBA/2 mice concentrated their licking exclusively within the initial 30-sec following pellet deliveries, regardless of FT interval length. Peak intoxication at FT-5 was associated with a 3-fold increase in first bout size, a doubling of % total intake consumed within the first bout, and a 2-fold escalation in the rate of drinking onset (licks/min) in C57BL/6 mice only. In contrast, the 5E drinking typography of DBA/2 mice remained relatively fixed across FT intervals of the ascending limb, resulting in a lower peak BEC in this non-preferring strain. Although the peak interval of SIP (FT-5) culminates in elevated ethanol intake and intoxication in both C57BL/6 and DBA/2 strains, significant HPA axis activation and expression of binge-like drinking typographies are observed only in the ethanol-preferring C57BL/6 mice.

Title: Ethanol intake under social circumstances or alone: Impact of age, sex, social activity and social anxiety.

Authors: *E. M. TRUXELL, L. P. SPEAR, E. I. VARLINSKAYA
Binghamton Univ., Binghamton, NY

Abstract: Alcohol use is normative among American adolescents, with drinking typically occurring in social situations. Recent studies in laboratory rodents suggest that responsiveness to certain desired effects of ethanol may be influenced by social context, with these influences being more pronounced during adolescence than in adulthood. Therefore, the present study was designed to assess the impact of drinking alone or in a social group on ethanol intake in group-housed adolescent and adult male and female rats. Another aim was to investigate whether individual differences in baseline levels of social activity and anxiety influence subsequent ethanol intake. On postnatal day (P) 30 or P70, levels of social activity and anxiety were assessed using a modified social interaction test. Animals were then given a 30-min drinking session every other day (six sessions) from P36 to P46 for adolescents and P76-86 for adults. During each session, animals were given access to 10% ethanol in “supersac” (3% sucrose + 0.125% saccharin) solution in a novel cage. On alternating days for each animal, ethanol access occurred either alone or in a group of five littermates, with the drinking context on the first day counterbalanced for each age/sex group. Animals were not food or water deprived prior to these limited access sessions. All experimental sessions were videotaped for later scoring, with individual intakes in group sessions indexed as proportional time spent drinking per animal x total g EtOH consumed/body weight. Trunk blood samples were collected immediately after the last session, and BECs determined. In general, adolescents drank more than adults, and females demonstrated higher intake than males regardless of age. Adolescent males, adult males and adult females
consumed more ethanol under social than alone circumstances. In contrast, adolescent females showed notable increases in ethanol intake under alone test circumstances. Highly socially active adolescent males demonstrated elevated levels of ethanol intake relative to their low and medium socially active counterparts when drinking in groups, but not when drinking alone. In adolescent females, level of social anxiety was associated with their intake under social circumstances, with highly socially anxious females consuming more ethanol than less socially anxious animals – an effect not seen under alone drinking conditions. In adults, neither social activity nor social anxiety predicted drinking behavior, suggesting that responsiveness to social stimuli exerts a substantial impact on “social drinking” during adolescence, but not in adulthood.

Title: Kappa-opioid receptors in neurons expressing the dopamine transporter mediate ethanol preference but not escalation of ethanol intake or binge drinking in mice.

Authors: *K. L. SMITH, A. VAN'T VEER, C. S. JOHN, E. I. SYPEK, W. A. CARLEZON JR., B. M. COHEN, A. J. BECHTHOLT-GOMPF
Harvard Med. School, Dept. of Psychiatry, McLean Hosp., Belmont, MA

Abstract: An important role for endogenous opioids in regulating the rewarding value of ethanol (EtOH) has been established both by findings using opioid antagonists in preclinical studies and by the effective clinical use of non-selective opioid antagonists in the treatment of alcoholism. The critical involvement of mu- and delta-opioid receptors is reported; however, the role of kappa-opioid receptors (KORs) requires further clarification, as changes in KOR functionality can both contribute to and diminish EtOH reward. Here, using cell type specific KOR deletion, we investigated the role of KORs in the expression of three types of ethanol consumption: 1) preference for EtOH, using a 2 bottle choice paradigm, 2) acquisition of moderate to excessive drinking (escalation drinking) and 3) binge drinking, using the drinking in the dark (DID) paradigm.
Methods: For selective ablation of KORs in dopamine transporter (DAT) containing neurons, we crossed our floxed KOR mice to DAT-Cre mice (mice expressing Cre recombinase under the control of the DAT promoter). Separate cohorts of female mice were used for each experiment. Two bottle choice: mice were given access to tap water through two sipper tubes for 4 days (acclimation). During the choice phase of the experiment, one of the two water bottles was replaced with a bottle containing EtOH in increasing concentrations (3%, 6% and 10%, 15% v/v). Escalation drinking: mice were acclimated to tap water through two sipper tubes for 4 days, before intermittent EtOH (15% v/v) access; mice were subjected to 24-hour cycles of ethanol access and deprivation for 14 days. DID: Water bottles were replaced with a 20% (v/v) EtOH solution sipper tube daily for 2h, presented 3h after lights out. After 6 days (acquisition), mice were given ethanol access for 4 h.
Results: Floxed KOR DAT-Cre+ (DAT neuron KOR knock-out) mice demonstrate a lower preference for EtOH compared to their littermates that lacked Cre in the two-bottle choice paradigm. No difference was detected between genotypes in escalation of EtOH intake or in

binge EtOH drinking (DID).
Conclusions: These data indicate that KOR activation contributes to the rewarding value of EtOH and that EtOH preference is mediated, at least in part, by regions expressing DAT, which would include the VTA. Although KOR deletion decreases preference for EtOH, this effect appears to be overcome when EtOH intake increases from low levels to moderate/excessive intake. Taken together these findings suggest that KORs in regions expressing DAT may mediate vulnerability to low and moderate intake, but play a negligible role in the regulation of excessive EtOH intake.

Title: During early ontogeny age and Picrotoxin determine ethanol intake and reinforcement, and whether ethanol is aversive or appetitive

Authors: *S. K. SANDERS, D. WATERS, A. GOLDBERG, N. ARANA, T. VILLALUNA, D. MENDOLA, F. LIRIANO, N. E. SPEAR
Binghamton Univ, SUNY, BINGHAMTON, NY

Abstract: Ethanol (EtOH) intake is high in the infant rat. Blood EtOH concentrations (BECs) of 300 mg% have been found after 30 min of drinking. EtOH intake does not directly reflect EtOH reinforcement; they often have been dissociated empirically. EtOH can condition aversions, but EtOH intake of doses that can condition aversions has been recorded. EtOH acts as a GABA agonist, and GABAergic drugs have been found to affect EtOH-related behavior. GABA function changes throughout early development, which could explain ontogenetic changes in EtOH intake. To assess the relationship between EtOH intake and reinforcement during infancy and the possible role of GABA, infant rats were given multiple EtOH exposures on postnatal day

6 (P6)-P10 or P12-P16. These ages differ in intake when EtOH is given by the technique of " consume off the floor" (COF), a self-administration paradigm. In the present experiment pups in the younger and older groups were given EtOH or water (H20). Intake sessions occurred every 24 hrs and were 20 min long. 48 hrs after the last intake session all pups were given an injection of Picrotoxin (PTX), a GABAA antagonist, prior to a test of H20 ingestion. In the younger group, pups previously given EtOH consumed more H20 at test than pups previously given H20. In the older group pups previously given EtOH ingested less H20 at test than pups previously given H20. In the younger group, PTX decreased intake of H20 regardless of what they were given previously, and his was more evident with previous EtOH. In the older group (P12-P16), PTX did not affect intake of H20 in pups previously given EtOH, but it did decrease H20 intake on P18 in pups given H20 on P12-P16. The younger infants appeared to condition acceptance of EtOH and the older infants appeared to condition aversion to EtOH. Since PTX decreased H20 intake on P18 and slightly on P12, additional P12 and P18 pups were given an injection of PTX prior to their first exposure to H20. PTX did not affect intake of H20 at P12 or P18 in pups given neither EtOH nor H20 previously. PTX apparently altered the effects of prior testing experience in general. Since PTX did not increase H20 intake in P18 pups given EtOH previously, it apparently did not affect aversive conditioning. Overall, the younger group ingested more EtOH and greater EtOH reinforcement was seen in the younger rats on P12, whereas the older group had lower EtOH intake on P12-P16 and they showed an EtOH aversion on P18. Taken together this suggests that EtOH is appositively reinforcing in the younger infants, but aversive in the older infants.

Title: Continuous intravenous caffeine infusions dose-dependently increase the motivation to obtain alcohol in rats.

Authors: *S. JONES, E. GARCIA, B. L. RINDT, M. I. PALMATIER
Psychology, Kansas State Univ., Manhattan, KS

Abstract: Caffeine (CAFF) and alcohol (ETOH) are self-administered simultaneously in human subjects. In pre-clinical models the bitter taste of CAFF reduces oral self-administration of ETOH, however bolus CAFF injections increase ETOH intake as well as motivation to obtain ETOH in rats. The present study investigated the effects of continuous intravenous (IV) experimenter-administered CAFF infusions on ETOH self-administration in order to more closely approximate the time course of co-administration in humans. ETOH drinking was initially established via intermittent access drinks of ETOH (20% v/v) in the home cage, with water freely available throughout this initiation phase. Once stable intake levels were reached, rats were briefly water restricted and shaped to respond for water in operant conditioning chambers that were fitted with two levers and two liquid dippers. Water was available in each dipper for pressing the lever located directly above that dipper on a fixed-ratio 1 (FR1) reinforcement schedule. Rats were then implanted with IV jugular catheters and allowed to recover for 7-10 days. During recovery, rats were randomly assigned to one of 2 groups [CAFF (1.36 mg/kg/session) or saline (SAL, 0.9%)] with the preference for the left and right levers balanced across groups. For each rat, one lever/dipper was assigned ETOH and the other water, with the constraint that preference for each dipper did not differ in either group. In subsequent tests, ETOH and water were available under an FR1 schedule before being shifted to an FR2 schedule. Rats received IV infusions of either CAFF or SAL every minute of a 60 minute session. CAFF significantly increased responding for ETOH under the FR2 schedule, but did not alter responding for water. Rats were then shifted to a progressive ratio schedule and CAFF concentrations were manipulated in order to determine the relationship between IV CAFF dose and the motivation to obtain ETOH. CAFF dose-dependently increased motivation to obtain ETOH, and preliminary findings suggest that the peak CAFF dose in this paradigm is approximately 5 mg/kg/h. These findings suggest that IV CAFF increases ETOH self-administration and motivation to obtain ETOH when CAFF is administered in conjunction with access to ETOH. Future studies will investigate whether CAFF will increase the motivation to obtain ETOH when oral ETOH and IV CAFF are both contingent upon operant behavior.

Title: Gaboxadol infusion in the nucleus accumbens shell decreases ethanol self-administration in mice

Authors: *M. RAMAKER[1], M. N. STRONG[1], M. M. FORD[1], D. A. FINN[1,2]
[1]Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR; [2]VA Med. Res., Portland, OR

Abstract: Recent in vitro studies suggest that recombinantly expressed GABAA receptors containing the δ subunit may show enhanced sensitivity to low doses of ethanol (i.e., 3 - 30 mM), when compared to receptors without the δ subunit. The δ subunit-containing GABAA receptors are thought to be located exclusively in the extrasynaptic space and contribute to tonic inhibition. Previous research in our lab has found that systemic injections of gaboxadol (THIP), a GABAA receptor agonist selective for the δ subunit, dose-dependently reduced intake of 10% (v/v) ethanol (10E) in a 2-bottle choice procedure (both 24 hr access and 2 hr access). In order to elucidate which brain regions may be underlying this effect, the present study aimed to examine the effect of a nucleus accumbens (NAc) shell infusion of THIP on 2 hr ethanol intake in an identical experimental setup. The NAc shell was chosen based on evidence in rats in which a conditional knockdown of the δ-subunit in the NAc shell reduced ethanol self-administration. In the current study, C57BL/6 (B6) male mice had 2-hour access to 10E and water beginning two hours into their dark cycle. Following approximately 4 weeks of stable ethanol intake, mice were surgically implanted with bilateral cannulae aimed at the nucleus accumbens shell. Following recovery from surgery, stable ethanol intake was re-established (2.7 g/kg/2 hr). Mice received a bilateral infusion of 0 or 500 ng (in 200 nl acsf) THIP per side into the NAc shell (n=11, within-subjects design), with a week between infusions. Infusion of THIP led to a 51% decrease in ethanol self-administration ($p = 0.008$). Importantly, these results indicate that activation of GABAA receptors in the NAc shell mimicked the effect seen following systemic THIP administration and that the δ subunit-containing GABAA receptors in the NAc shell may be an important mediator of ethanol reinforcement.

Title: The role of midbrain dopamine neurons in mediating alcohol drinking behaviors

Authors: *B. JUAREZ[1,2], A. K. FRIEDMAN[3], D. CHAUDHURY[3], J. J. WALSH[2], M. CRUMILLER[2], M.-H. HAN[3]
[1]New York, NY; [2]Neurosci., [3]Pharmacol., Mount Sinai Sch. of Med., New York, NY

Abstract: In contrast to most drugs of abuse, such as cocaine, human alcohol dependence research has shown that there are multitudes of factors that predispose an individual to alcoholism or alcohol abuse. This suggests that there may be a "susceptibility" to alcohol preference that could ultimately lead to alcohol dependence. To understand the physiological properties that underlie this susceptibility to alcohol preference, we used C57BL/6J male mice, a strain that has a well-established alcohol drinking preference behavior. Previous studies have shown that this strain of mice displays a bi-model distribution of low and high preference alcohol drinking phenotypes. Using a two-bottle choice (2-BC) paradigm with increasing concentrations of alcohol (24 hr access), we were able to clearly define the low preference drinkers and the high preference drinkers by their statistically different consumptions of alcohol. We then performed *in vivo* electrophysiological recordings from dopamine neurons in the ventral tegmental area (VTA), a key component of the mesolimbic reward circuit, between the two groups. Surprisingly, we found that low preference drinkers have a significantly higher firing rate, higher bursting frequency and percent time bursting in VTA dopamine neurons as compared to the high preference drinkers. To further investigate this phenomenon, we used optogenetic techniques to manipulate firing of VTA cells *in vivo* to mimic the firing changes we observed in low preference drinkers. Using a burst/phasic stimulation protocol, we show that activation of channel-rhodopsin (ChR2)-infected VTA neurons causes a significant decrease in alcohol drinking preference and consumption during a four-day binge drinking paradigm. This occurs in both one-bottle choice (1-BC) and 2-BC in alcohol consumption and preference, when compared to control mice and mice that received a tonic stimulation pattern. We are currently using halorhodopsin to decrease the firing of these cells in order to observe changes in alcohol drinking behavior. These studies, and continuing work, will provide highly useful information about cell type-specific functional roles of the brain's reward circuit in mediating alcohol drinking behaviors.

Title: MetBDNF polymorphism promotes persistent alcohol drinking behavior in mice.

Authors: *V. WARNAULT, E. DARCQ, D. RON
The Ernest Gallo Clin. and Res. Ctr., Emeryville, CA

Abstract: The brain-derived neurotrophic factor (BDNF) plays an important role in neurogenesis and neurodevelopment, as well as in learning and memory (1). A single nucleotide polymorphism (G196A) in the BDNF gene results in an amino acid substitution of Valine (Val) for Methionine (Met) in the pro-region of BDNF causing a deficit in neuronal activity-dependent release of the neurotrophic factor (2). An average of 23% of the world population carries the MetBDNF allele (3) and this polymorphism has been associated with the severity level of several psychiatric disorders (1-2).

We generated data to suggest that BDNF is part of a homeostatic pathway that gates the transition from moderate to excessive alcohol drinking (4-7). Therefore, we hypothesized that the protective role of the growth factor against the development of adverse phenotypes such as excessive alcohol intake will be diminished in carriers of the MetBDNF allele. To test this hypothesis, we generated homozygous knock-in mice carrying the MetBDNF allele on a C57Bl/6J background (MetBDNF), and tested whether this polymorphism promotes excessive alcohol drinking in adult male mice.

Using a paradigm of intermittent access to 20% alcohol (v/v, 2 bottle choice), we found that the MetBDNF mice drink a higher level of alcohol than wild type (WT) mice. Interestingly, the MetBDNF but not WT mice continued to consume alcohol even when the solution was adulterated by quinine (0.1-0.3g/l). Importantly, this difference was not due to a change in quinine palatability. These data suggest that carrying the MetBDNF allele results in a persistent consumption of high levels of alcohol despite negative consequences (e.g., ingestion of an unpalatable solution). We also found that the higher level of alcohol intake in MetBDNF mice was not due to faster alcohol metabolism. Importantly, the two genotypes did not differ in general compulsivity-like behavior as measured by the T-Maze. Furthermore, MetBDNF and WT mice consumed the same amount of a saccharin solution (0.03%w/v) even after adulteration by quinine (0.1-0.3g/l), indicating that the persistent alcohol intake by the MetBDNF mice is specific to alcohol and is not due to a general increase in motivation to drink a rewarding solution. Together, our results suggest that the MetBDNF allele increases the risk for developing alcoholism by promoting compulsive alcohol intake.

Title: Effect of chronic alcohol use on steady state plasma levels of stavudine, lamivudine and nevirapine in HIV/AIDS patients in Uganda using chronic alcohol-use biomarkers

Authors: *G. BBOSA
Dept Pharmacol & Therapeut., Makerere Univ. Med. Sch., Kampala, Uganda

Abstract: Chronic alcohol consumption by some HIV/AIDS patients on ARVS may affect their therapeutic outcome due to the interaction of ethanol and the drugs. The study determined the effect of chronic alcohol use on the steady state plasma drug concentrations (therapeutic window) of d4T, 3TC and NVP in the HIV/AIDS patients. A longitudinal cohort using repeated measures design with serial measurements model was used. The alcohol-use bioamrkers were used to screen the patients and also to standardise the gender differences in alcohol use. A total of 41 patients (26 alcohol group and 15 control group) were followed up for 9 months with sampling done at 3 month intervals. Plasma was obtained by centrifuging. The Shimadzu Class-VPTM HPLC Chromatography data system version 6.1 was used to measue the plasma drug levels of d4T, 3TC and NVP. Data was analysed using the SAS 2003 version 9.1 statistical package with the repeated measures fixed model and the means were compared using the student t-test. Generally the mean steady state plasma drug levels of d4T and 3TC were higher than the reference ranges in both the control and alcohol-use groups but the plasma drug levels in the alcohol group were lower than in control group during the 9 months period of follow-up though the difference was not statistically significant ($p>0.05$). The mean steady state plasma drug levels of NVP in both groups were within the reference ranges but though the plasma drug levels were higher in the alcohol group as compared to the control group and there was no significant

difference ($p<0.05$) in the groups. Chronic alcohol use by the HIV/AIDS patients may reduce the steady state plasma
drug levels of d4T and 3TC but may increase the NVP drug levels in the patients.

Title: Ethanol intake is insensitive to dihydromyricetin in adult rats with a long history of established alcohol self-administration.

Authors: *D. J. WOODWARD, A. V. AZAROV
Neurosci. Res. Inst. of North Carolina, WINSTON-SALEM, NC

Abstract: The aim of this work was to study the influence of dihydromyricetin (DHM) on established ethanol intake in adult rats. A flavonoid component of anti-hangover herbal medicines and a relatively new compound for US, DHM (~6.7 mg/kg/day in drinking fluids) was recently shown to suppress ethanol intake by ~80% in young rats with initial weight of 200-250 g, after 6 weeks (PND ~49-56 to ~91-98) of ethanol vs. water drinking under alternate-day access in “Wise-Simms procedure” (Shen et al., 2012, J. Neurosci., 32, 390-401). Upon drinking in the same access conditions, ethanol self-administration was sensitive after 1.5-months, but resistant after 3-4 months, to pairing with normally aversive influence of quinine (Hopf et al., 2010, Alcohol. Clin. Exp. Res., 34, 1565-73). In current study, Sprague Dawley rats weighing 400-450 g were cage and spout trained for 1 week and then allowed to drink 20% v/v EtOH (20E) in choice with water on Mon-Wed-Fri, with access to only water on remaining days, for 16 weeks, in 15-hr sessions. On week 16, EtOH intake was 3.3 g/kg and preference ~ 50%, total fluid intake was ~ 38 ml/kg and very close on both alcohol and water days. Then for 2 weeks, DHM (0.15 mg/ml) was added on alcohol days to both 20E and water. Total fluid intake under DHM was similar to pretreatment weeks, and between alcohol and water days, with the respective dose of self-administered DHM at ~5.7 mg/kg/day. EtOH intake was 2.8 and 3.4 g/kg, and preference - 47 and 60%, on DHM weeks 1 and 2. Our finding is that in adult rats with a long experience of alcohol self-administration, ethanol intake under DHM showed only slight downward trend in the 1st week of treatment followed by a recovery during 2nd week, indicating

an overall resistance to DHM suppression. These data, together with those already published suggest that therapeutic potential of dihydromyricetine for alcohol use disorders may depend on the length of a drinking history and / or the age of an individual. (AA020676 to DJW)

Title: Activation of glutamate transporter 1 attenuates relapse to alcohol- seeking behavior in alcohol-preferring rats

Authors: A. M. QRUNFLEH, A. ALAZIZI, S. N. SREEMANTULA, *Y. SARI
Univ. of Toledo, Col. of Pharm., Toledo, OH

Abstract: Relapse to alcohol-seeking behavior depends on increased glutamate transmission in key regions of the mesocorticolimbic motive circuit, including prefrontal cortex (PFC) and nucleus accumbens (NAc). Extracellular glutamate is regulated by a number of glutamate transporters in various brain regions. Of these transporters, glutamate transporter 1 (GLT1, also termed excitatory amino acid transporter 2, EAAT2), is responsible for the uptake of the majority of extracellular glutamate. We have recently reported that ceftriaxone (i.p.), a b-lactam antibiotic known to elevate GTL1 expression, reduces alcohol intake in alcohol-preferring (P) rats (Sari et al., 2011). We investigated here whether ceftriaxone-induced GLT1 upregulation or activation attenuates relapse to alcohol-seeking behavior. We found that P rats that have been exposed to free choice of 15% and 30% alcohol for 5 weeks and treated with ceftriaxone (50 and 100 mg/kg, i.p.) during the last 5 days of the two-week deprivation period showed a reduction in alcohol intake upon relapse that persisted for at least 10 days. Moreover, ceftriaxone-mediated attenuation in relapse to alcohol drinking was associated with upregulation of GLT1 level in PFC and NAc core. The upregulation of GLT1 level was found only at the higher dose of ceftriaxone, which suggests that the lower dose may have other pharmacological effects that cause reduction in alcohol intake. In addition, ceftriaxone has no effect on relapse to sucrose-seeking behavior. Given previous work indicating that up-regulation of GLT1 attenuates cue-induced reinstatement of cocaine-seeking behavior in rats (Knackstedt *et al.,* 2010; Sari *et al.,* 2009) and reduces

alcohol consumption in P rats, GLT1 is considered now as potential therapeutic target for treatment of alcohol dependence.

Title: Effects of ceftriaxone on the acquisition and maintenance of ethanol drinking in peri-adolescent and adult female alcohol-preferring (P) rats

Authors: *P. RAO[1], J. E. TOALSTON[2], A. ALAZIZI[1], Y. SARI[1], R. L. BELL[2]
[1]PHARMACOLOGY, UNIVERSITY OF TOLEDO, TOLEDO, OH; [2]Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Increased glutamatergic neurotransmission has been demonstrated to mediate the reinforcing properties of drugs of abuse, including ethanol (EtOH). We have recently shown that administration of ceftriaxone, a β-lactam antibiotic known to upregulate glutamate transporter 1 (GLT1) levels/activity, decreased the maintenance of EtOH intake in male adult alcohol-preferring (P) rats (Sari et al 2011). In the present study, we tested whether ceftriaxone administration would reduce the acquisition and maintenance of EtOH drinking in adolescent and adult female P rats. Adolescent (~35 days of age) and adult (~75 days of age) EtOH-naïve female P rats were used in this study. Animals were treated with 200 mg/kg ceftriaxone for 7 days prior to acquisition to and during the maintenance of EtOH intake in both adolescent and adult female P rats. The results show that pretreatment with ceftriaxone reduced the acquisition of EtOH intake compared with controls in adolescent, but not adult, rats. However, there was increased water intake after ceftriaxone treatment in both age groups as well. Ceftriaxone treatment significantly reduced the maintenance of EtOH intake compared with controls in both animals that started as adolescents and adults. As before, water intake was increased following ceftriaxone treatment in both groups. Reductions in EtOH intake by ceftriaxone were inversely associated with the upregulation of GLT1 protein levels in both the nucleus accumbens (~25% in

rats that started at both ages) and prefrontal cortex (~65% in rats that started as peri-adolescents and ~50% in those that started as adults). These findings provide further support for continued research examining GLT1-associated mechanisms for the treatment of alcohol abuse and dependence.

Title: Novelty- seeking behaviors and the escalation of alcohol drinking after abstinence are controlled by mGluR5 receptors on dopaminoceptive neurons.

Authors: *J. RODRIGUEZ PARKITNA, M. SIKORA, S. GOLDA, R. PRZEWLOCKI
Inst. of Pharmacol. of the Polish Acad. of Sci., Krakow, Poland

Abstract: Novel experiences activate the brain's reward system in a manner similar to drugs of abuse, and high levels of novelty- and sensation-seeking behavior have been associated with increased susceptibility to alcohol and drug abuse. Here we investigate how glutamatergic modulation of dopaminoceptive neurons affects novelty seeking and alcohol drinking in a mouse model with selective knock-down of the metabotropic glutamate receptor 5 (mGluR5) in neurons expressing D1 dopamine receptors. Mice harboring a transgene expressing microRNA hairpins against mGluR5 mRNA under the control of the D1 dopamine receptor gene promoter ($mGluR5^{KD\text{-}D1}$) showed no behavioral deficits and exhibited normal anxiety levels and learning abilities. However, $mGluR5^{KD\text{-}D1}$ animals showed reduced locomotor activity when placed in a novel environment and exhibited decreased interaction with a novel object. Moreover, unlike control animals, mutant mice did not perform instrumental responses under the operant sensation-seeking paradigm, although they learned to respond for food normally. When $mGluR5^{KD\text{-}D1}$ mice were provided access to alcohol, they showed similar patterns of consumption as wild-type animals. However, mutant mice did not escalate their alcohol consumption after a period of forced abstinence, but control mice almost doubled their intake.

These data identify mGluR5 receptors on D1-expressing neurons as a common molecular substrate of novelty-seeking behaviors and behaviors associated with alcohol abuse.

Title: Clozapine inhibition of alcohol intake in Syrian golden hamsters: selectivity, motivation and reward

Authors: *D. GULICK[1], L. BONVINI[1], E. TEMPLETON[1], A. SONSTEGARD[1], D. BUCCI[2], A. GREEN[1]
[1]Psychiatry Dept., Dartmouth Med. Sch., LEBANON, NH; [2]Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Introduction: Although the atypical antipsychotic drug clozapine (CLOZ), unlike other antipsychotics, effectively reduces alcohol intake in patients with schizophrenia (SCZ), it is prescribed infrequently because of its severe side effects. CLOZ also decreases free access alcohol drinking in the Syrian golden hamster, an animal model of alcohol drinking, while haloperidol (HAL), an antipsychotic that does not limit alcohol drinking in SCZ, has no effect on alcohol drinking in the hamster. In order to develop novel therapeutics based on CLOZ's action, we sought to elucidate the basis of CLOZ's effect on alcohol intake in the hamster. We first tested whether CLOZ would reduce sucrose or saccharin intake, as well as alcohol intake, to determine if it has a selective effect on drug rewards vs. natural rewards. Next, to determine whether CLOZ reduces alcohol intake by interfering with the motivation to consume alcohol or by reducing alcohol-associated reward, we tested the effects of CLOZ vs. HAL on operant responding and conditioned place preference (CPP) for alcohol or sucrose. Methods: In Experiment 1a, animals were given free access to food and two bottles - one water bottle and the other containing either a solution of sucrose (15.5 g/L) or saccharin (0.732 g/L). In Experiment 1b, animals were given free access to food and three bottles - one water bottle, one 15% v/v alcohol bottle, and the other containing either a high concentration solution of sucrose (210 g/L) or saccharin (0.732 g/L). Drug treatment consisted of 14 daily injections of 8 mg/kg CLOZ or

vehicle after fluid consumption levels steadied. In Experiment 2, we measured the effects of CLOZ or HAL on operant lever pressing for water, sucrose, or alcohol rewards. Finally, in Experiment 3, we tested the effects of CLOZ or HAL on CPP for alcohol or sucrose. Results: CLOZ was more effective at reducing alcohol intake than either sucrose or saccharin intake. HAL, but not CLOZ, reduced lever pressing for alcohol and sucrose. HAL also completely blocked CPP, whereas CLOZ produced only a modest, non-significant attenuation of CPP. Discussion: CLOZ selectively reduces alcohol intake without significantly impacting the intake of natural rewards. Further, the decreased alcohol intake in response to CLOZ treatment occurs without a change in alcohol-seeking behaviors or alcohol-associated reward, supporting the hypothesis that CLOZ, unlike HAL, may decrease alcohol drinking by ameliorating dysfunction of the brain reward circuit without blunting the ability of the reward circuit to respond to rewarding stimuli.

Abstract: Selective and acute blockade of the dopamine (DA) D3 receptor by SB-277011A attenuates ethanol (EtOH) preference, intake, and lick responses in EtOH-preferring rats. However, alcohol consumption that leads to abuse is often marked by binge drinking, characterized as bringing blood EtOH levels to ≥ 80mg/dl within two hours of the initial drink. It is unclear if brain mechanisms implicated in EtOH reward are equally implicated in EtOH binge

consumption and abuse. Therefore, the present study utilized the "Drinking-in-the-Dark" paradigm to examine the acute effects of SB-277011A, on binge consumption of EtOH in mice. Male C57BL/J6 mice were given access to 2% EtOH (diluted in near beer) 3hrs into their dark cycle and were allowed to drink EtOH for 2hrs. The total EtOH consumed during this time was measured for 7consecutive days to provide a baseline. On test day, the mice were given i.p. injections of either vehicle (10% 2-hydroxypropyl-β-cyclodextrin in 0.9% saline) or SB-277011A (15 or 30 mg/kg), thirty minutes prior to their drinking session. The results demonstrated that mice voluntarily brought their blood alcohol levels to ≥ 80mg/dl. In addition, a single i.p. injection of 15 mg/kg i.p. of SB-277011A produced a significant decrease in EtOH consumption. These data show that the acute administration of SB-277011A decreases voluntary binge consumption of EtOH and provide evidence that the DA D3 receptor plays an integral role in binge drinking-in-the-dark in mice.

Title: Subchronic anabolic steroid administration affects voluntary alcohol drinking in alcohol preferring AA rats

Authors: S. KAILANTO, *K. KIIANMAA, T. SEPPÄLÄ
Dept. of Alcohol, Drugs and Addictions, Natl. Inst. for Hlth. and Welfare, Helsinki, Finland

Abstract: Introduction: Alcohol abuse and dependence with the resulting medical and social harm remain among the greatest substance abuse problems worldwide. Furthermore, a large number of young adults abuse anabolic androgenic steroids (AASs). Whether the abuse of AAS constitutes a risk factor for abuse of other intoxicants and drugs, or vice versa, is still unknown. This question is, however, of importance, since several surveys conducted young adults and adults not connected to sports, have revealed that AAS use may be concomitant with use of alcohol or drugs. This type of mixed-use probably involves more than a desire to enhance the users' appearance or sports performance. Several studies have shown that chronic AAS use may affect behaviour by influencing neuronal activity and plasticity. The specific aim of the present

study was to assess if nandrolone decanoate, the AAS, exposure modulates the voluntary ethanol intake by alcohol preferring AA (Alko Alcohol) rats.
Methods: Three months old AA rats were placed into single wire mesh cages, where food and water (n=24), or food and a free choice between 10% (v/v) ethanol and water (n=24) were continuously available. After four weeks of ethanol intake, nandrolone decanoate (20 mg/kg i.m.) or vehicle oil was administered to the rats every other day, five times in total. Ethanol and water consumption measurements were continued for four weeks after the last steroid injection.
Results: The results showed that all ethanol drinking animals achieved stable consumption levels of ethanol (4.9 g/kg/day) during the first four weeks. The ten day nandrolone treatment decreased ethanol intake (3.0 g/kg/day) compared to the vehicle oil treated animals (4.4 g/kg/day). Intake of ethanol stayed on a lower level also during the four weeks following administration of the drug, although the difference between the groups narrowed during the last week.
Discussion: Suppression of ethanol intake after administration of nandrolone decanoate suggests that AAS treatment may modify the rewarding effects of ethanol in alcohol preferring rats. Nandrolone treatment may therefore be used in certain conditions to reduce intake of ethanol. Since ethanol consumption remained on a reduced level after discontinuation of the nandrolone decanoate treatment, the anabolic steroid may induce long lasting changes in the functioning of the brain.

Title: Microstructure of binge-like ethanol drinking in a high drinking selected mouse line

Authors: *A. M. BARKLEY-LEVENSON[1,2], J. C. CRABBE[1,2]
[1]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Portland Alcohol Res. Ctr., VA Med. Ctr., Portland, OR

Abstract: The High Drinking in the Dark (HDID) mouse line was selected for high blood ethanol concentration (BEC) following limited access to an ethanol solution. These mice voluntarily drink to intoxicating BECs in a short period of time, and consequently represent a genetic animal model of binge-like drinking. Recently, we have shown that these mice have a larger average bout size than their control line, without differing in average bout duration, when tested in the BioDAQ Episodic Intake Monitoring system on a 4 day Drinking in the Dark (DID) procedure. This suggested a possible genetic difference in ethanol drinking efficiency (e.g. lick rate or lick volume), and the present study sought to address this possibility. Male HDID-1 and HS/Npt (HS; heterogeneous control line) were given a 4 day limited-access DID test while housed in lickometer chambers that record each contact with the drinking tube (licks). During the 4 hours of access on the final test day, HDID-1 mice drank significantly more g/kg ethanol, had a greater total number of licks, and reached higher BECs than the HS mice. The lines did not differ significantly in overall lick rate or lick volume. Drinking bout structure was examined, with a bout defined as at least 20 licks with no more than one minute between licks. HDID-1 mice had a significantly larger average bout size (licks/bout) than HS mice. This was due to a significantly larger bout size during the first 2 hours, but not during the second 2 hours. These results differ from those obtained using the BioDAQ system, wherein genotypic differences in bout size were primarily observed during the latter half of the drinking session. We also observed a trend towards the first bout in the session being larger on average in HDID-1 mice than HS mice, suggesting that HDID-1 mice might be more initially receptive to ethanol than HS mice. HDID-1 and HS mice did not differ significantly in number of bouts or average bout duration. Overall, these results replicate the previously reported larger bout size of the HDID-1 mice than the HS mice, and suggest that the greater ethanol consumption by the HDID-1 mice than the HS mice does not seem to be due to consistent differences in lick rate or lick volume. Additionally, the temporal pattern of genotypic differences in bout size may vary depending on the continuous consumption recording system used and subsequent total intake. Title: Effects of ivermectin on free-choice maintenance and relapse ethanol drinking in two rat lines selectively bred for high alcohol preference

Authors: *K. M. FRANKLIN[1,2], R. L. BELL[2], W. J. MCBRIDE[2,3]
[1]Indiana Univ. Sch. of Med., INDIANAPOLIS, IN; [2]Psychiatry, [3]Biochem., IU Sch. of Med., Indianapolis, IN

Abstract: On-going studies in our, and other, labs have implicated purinergic P2X4 receptors in ethanol (EtOH) drinking. The objective of the current study was to assess the ability of systemic (i.p.) and central (intracerebroventricular [i.c.v.]) exposure to the P2X4 receptor positive allosteric modulator ivermectin (IVM) to reduce the maintenance of and relapse to EtOH drinking in two rat lines selectively bred for high EtOH consumption. Methods: Experiment 1: Adult, male high-alcohol drinking replicate (HAD1/HAD2) rats were provided 24-hr free access to 15% EtOH, water, and food. Following stable EtOH drinking levels, rats (n=8/dose) were injected (i.p.) for 5 consecutive days with 1.5-7.5 mg/kg IVM or a vehicle (10% propylene glycol into sterile saline) 30 min prior to the dark cycle. EtOH intake (g/kg) was assessed 1, 4, and 24 hrs following IVM treatment. Following the 5 test sessions, rats were maintained on the 24-hr EtOH access protocol without IVM treatment to serve as a “washout period” and assess EtOH drinking recovery. Rats then were EtOH-deprived for a 2-week period. These methods were repeated to assess IVM’s effects on relapse to EtOH drinking. Rats received the same IVM dose in both test-phases. Experiment 2: Adult, female HAD2 rats were provided 2-hr scheduled access to 15% EtOH, with free food and water access. Following stereotaxic cannula implantation into the lateral ventricle and stable EtOH drinking levels, rats (n = 5-7/dose) were infused i.c.v. for 5 consecutive days with 0.5-2.0 ug/ul IVM or a vehicle (10% propylene glycol into artificial cerebrospinal fluid) 30 min prior to the dark cycle. EtOH intake (g/kg) was assessed 2 hrs following IVM treatment. Results: Experiment 1: Systemic IVM treatment reduced on-going and relapse EtOH drinking in HAD1 and HAD2 rats (up to ~50% of vehicle-values) with the greatest effects occurring at 5.0 and 7.5 mg/kg IVM doses. However, these reductions were variable, due to several testing conditions, including rat line and test-phase. Also, the effects were time-dependent, with the greatest reductions relative to controls occurring 4 hrs after IVM treatment. Experiment 2: Central infusion with 2 ug/ul IVM revealed a trend toward reducing 2-hr EtOH drinking over the 5-day test period, up to ~30% of vehicle-values ($p = 0.06$). Conclusions: The current findings support several avenues of research implicating P2X4 receptors in EtOH-drinking behavior. Our results indicate that systemic and central IVM administration reduce EtOH intake in two rat lines genetically selected for high alcohol

preference. Overall, these findings suggest that an IVM-like compound could prove useful in treating alcohol abuse and dependence.

Title: Urocortin-1: Selective involvement in long-term alcohol consumption

Authors: *W. J. GIARDINO, M. M. FORD, A. E. RYABININ
Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Converging lines of evidence support a role for the neuropeptide urocortin-1 (Ucn1) in alcohol preference and reward. Earlier studies showed that, relative to wild-type littermates, genetic deletion of Ucn1 in mice on a C57BL/6J background dampened intake of 6% and 10% alcohol in a continuous access “two-bottle choice” (2BC) drinking procedure. However, we observed no effect of Ucn1 deletion in a limited access “drinking-in-the-dark” (DID) model, in which mice had access to a single bottle of 20% alcohol for 2-4 hours, beginning 3 hours into the circadian dark period. Because these procedures differed in several aspects, we investigated the relative importance of each variable in mediating Ucn1’s effects on alcohol drinking.
Experiment A used a continuous access 2BC procedure with 10-40% alcohol (four sessions at each concentration). Experiment B used the standard DID procedure (four sessions total), except access to alcohol was accompanied by access to water. Experiment C used an intermittent access 2BC procedure in which mice were offered 3-20% alcohol every other day for five weeks. Consumption in Experiment C was tracked using a lickometer apparatus, allowing for analysis of changes in the drinking microstructure across time.
In Experiment A, genetic deletion of Ucn1 dampened intake and preference of 20-40% alcohol, relative to wild-type littermates. In Experiment B, deletion of Ucn1 had only minor and sex-

specific effects on alcohol preference. In Experiment C, deletion of Ucn1 decreased 20% alcohol consumption during the first four hours of the session, relative to wild-type littermates. Importantly, this effect emerged only after several alcohol drinking sessions.
In conclusion, it appears that Ucn1 involvement in alcohol consumption depends on the extent of alcohol history, rather than alcohol concentration, concurrent water availability, or schedule of access. These findings lend further support for Ucn1's importance in the development of alcohol use disorders resulting from prolonged drinking.
Additional studies are currently aimed at evaluating whether Ucn1 plays a role in sensitivity to alcohol-induced sedation, and whether Ucn1's contribution to alcohol consumption can be explained by generalized effects on fluid intake, caloric intake, or taste reactivity.

Title: Caffeine reduces alcohol intake but increases nicotine self-administration in rats

Authors: *A. H. REZVANI[1], H. G. SEXTON[1], J. JOHNSON[1], C. WELLS[1], K. GORDON[1], L. LUMENG[2], J. ROSE[1], E. D. LEVIN[1]

Abstract: Caffeine, alcohol and nicotine are three of the most widely used psychoactive drugs in the world. They are often taken together. However, the interaction of caffeine, either promoting or inhibiting alcohol or nicotine self-administration, has not been well characterized. After the establishment of a stable alcohol intake in alcohol preferring (P) rats, the acute (0, 5, 10 and 20 mg/kg) and chronic (0, 20 mg kg for 10 days) effects of caffeine given subcutaneously (SC) or orally on alcohol intake and preference were determined. In addition, the acute effects of caffeine (0, 20 mg/kg given orally) on alcohol intake and preference after 4-day alcohol deprivation were evaluated. The acute effects of oral administration of caffeine (0, 20 mg/kg given) on saccharin (0.2%) preference was also assessed. Furthermore, we explored the effects of acute oral administration of caffeine on nicotine self-administration in Sprague Dawley rats. Acute SC

administration of caffeine (20 and 10 mg/kg) significantly reduced alcohol intake and preference at 24 hr. as well as saccharin intake in P rats. Caffeine also reduced alcohol intake following a 4-day alcohol deprivation. Chronic oral treatment with caffeine for 10 days reduced alcohol intake and preference with some signs of tolerance over that period. In contrast to its effects in reducing alcohol consumption, acute oral treatment with caffeine significantly increased rates of nicotine self-administration in Sprague Dawley rats. Caffeine and other adenosine receptor antagonists may hold promise for the treatment of excessive alcohol drinking. However, caffeine may be contraindicated with people who are trying to quit smoking given that it promoted nicotine intake in this preclinical study.

Title: Sprague-Dawley rats self-administer alcohol and show alcohol preference using the two-bottle choice intermittent access drinking model

Authors: *R. K. VASUDEVA[1], S. WARD[1], L. G. KIRBY[2]
[1]Pharmacol., [2]Anat. & Cell Biol., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Alcoholism afflicts 1 in every 13 US adults, and comorbidity with depression is common. Levels of serotonin (5HT) metabolites in both alcoholic humans and alcohol-preferring rat strains are lower compared to non-alcohol dependent counterparts. While strains of rats are bred for alcohol preference (P, sP, AA) and others (Wistar, Long-Evans) are more commonly used in alcohol studies, we wanted to demonstrate that the standard out-bred Sprague-Dawley (SD) rat can also develop a preference for alcohol. This strain of rat was selected to coincide with several studies examining models of depression and anxiety in our laboratory and others. Two groups (n = 8) of SD male rats were housed singly and placed on the intermittent-access (IA) two-bottle choice drinking paradigm. Within each group, an average of 5 rats demonstrated a natural preference for ethanol (EtOH) by week 5, with an average of 3 rats not consuming significant amounts of EtOH for the duration of the study. Rats that demonstrated a preference

for ETOH consumed up to 4g ETOH/kg/day, while those who did not show a preference consistently drank less than 0.5g ETOH/kg/day. After 8 weeks on the IA paradigm, Group 1 was transferred to an operant conditioning task for EtOH self-administration. For comparison, a third group of SD rats (n = 6) was trained to self-administer EtOH using a sucrose fading (SF) paradigm. Under a fixed ratio 1 (FR1) schedule, the EtOH concentration-effect curve for IA rats was shifted downward and rightward compared to the SF rats, indicating that experience with IA led to an increased schedule-controlled intake of EtOH at higher doses. Responding for EtOH was more similar between the IA and SF groups under a progressive ratio (PR) schedule, indicating that motivation to consume EtOH did not differ following the different training paradigms. Additionally, IA and SF rats could be divided into high and low responders based on their EtOH self-administration behavior. Future work will investigate drinking behavior and EtOH consumption following depletion of 5HT. We predict that levels of EtOH consumption will increase significantly above baseline levels following cerebral 5HT depletion, thus mimicking alcoholic-like behaviors. Overall, we found that SD rats demonstrate a natural preference for EtOH in the IA paradigm. We also showed that SD rats acquire EtOH self-administration in a similar manner to more commonly used rat strains using two established operant training paradigms. Interestingly, these results also revealed the presence of distinct high and low self-administering SD rats, representing the opportunity to further investigate neurobiological correlates to these two phenotypes.

Title: Social deprivation and social instability stress during adolescence modify anxiety-like behavior and plasma corticosterone, but not alcohol self-administration.

Authors: *P. E. OLIVEIRA, L. C. CASULA, P. C. BIANCHI, R. M. LEÃO, F. C. CRUZ, C. S. PLANETA
PANT, Univ. Estadual Paulista, Araraquara, Brazil

Abstract: Adolescence is a critical period of ontogeny which individuals of several species presents typical characteristics such as increasing in novelty-seeking, risk-taking and peer interaction behaviors. These characteristics could facilitate initial drug-seeking, enhancing the vulnerability to addiction in later stages of life. Epidemiological studies have shown links between early life stressors and future alcohol problems. Pre-clinical researches corroborate these evidences demonstrating that stress during adolescence enhances the behavioral effects of drugs of abuse. In this study we evaluated the influence of early life social stressors on alcohol self-administration, anxiety-like behavior and plasma corticosterone. Adolescent male Wistar rats were submitted to 15 days of social deprivation or social instability. During this period the control group was left undisturbed. Blood samples were collected twenty four hours after the last stress session and five minutes after elevated plus maze test (EPM test) from tail vein. EPM test were applied forty eight hours after the end of the stress protocol. Anxiety-like indices in the EPM (% of frequency of entries and time spent in the open arms of maze) were registered during five minutes. Then animals of three groups were subjected to ethanol (6%) or saccharin (0.05%) self-administration protocol. Progressive ratio schedule and 24h-unlimited access parameters of alcohol (6%) or saccharin (0.05%) reinforcement was analyzed. Rats submitted to chronic social stress have shown increased percentage of open-arms entries and time spent in open-arms compared to control group. Basal plasma corticosterone was not altered by stress, however, single reared animals showed a pronounced increase of corticosterone secretion in response to a novelty. Furthermore, alcohol and saccharin self-administration behavior were not modified by previous stress. In conclusion, social deprivation and social instability during adolescence rats promote anxiolytic-like behavior, alteration of HPA axis when animals are submitted to an unknown environment, but were not able to alter alcohol- and saccharin-seeking behavior.

Title: Expression of MicroRNA10a and target genes is up-regulated by psychological stress, and correlates with drinking behavior in heavy, but not moderate drinkers.

Authors: *R. D. BEECH[1], J. J. LEFFERT[1], A. LIN[2], K. A. HONG[1], J. HANSEN[1], S. UMLAUF[3], S. MANE[3], H. ZHAO[4], R. SINHA[1]
[1]Psychiatry, [2]W.M. Keck Fndn. Biostatistics Resource, [3]Ctr. for Genome Analysis, [4]Epidemiology and Publ. Hlth., Yale Univ. Sch. Med., New Haven, CT

Abstract: Background: Alterations in stress-related gene-expression may play a role in stress-related drinking and the risk for alcohol dependence.
Methods: Microarrays were used to measure changes in gene-expression in peripheral blood in subjects exposed to three types of personalized imagery: neutral, stressful (but not alcohol-related), and alcohol-related. Gene-expression was measured at baseline, immediately after, and 1 hour after stimulus presentation. Subjects were allowed to drink up to 750cc of beer in a taste-test during the hour following stimulus presentation in each imagery condition, and the amount of beer consumed was recorded. Gene-expression levels were compared in 2 groups of subjects categorized into heavy drinkers (HD, defined as regular alcohol use over the past year of at least 8 standard drinks/week for women and at least 15 standard drinks/week for men), and moderate drinkers (MD, defined as up to 7 standard drinks/week for women and 14 standard drinks/week for men). Expression of microRNA10 (miR-10a) was assessed by quantitative real-time PCR (qRT-PCR).
Results: After correction for multiple testing (FDR<0.05), 79 genes were identified that changed by > 1.3 fold in the HD group, but not the MD group, following exposure to stress. No changes were observed for any of these genes in either group following exposure to neutral or alcohol-related imagery. Pathway analysis suggested that many of these genes were positively regulated by miR-10a. MiR-10a expression was up-regulated following psychological stress in HD, but not MD subjects, and miR-10a levels were correlated (R^2= 0.59) with amount drunk in HD, but not MD subjects.
Conclusions: These results demonstrate that expression of miR-10a and several of its target genes can be regulated by acute psychological stress, and is correlated with stress-induced drinking in a laboratory setting. Alterations in miRNA expression may be one mechanism linking psychological stress with changes in both gene-expression and behavior.

Title: How does early life trauma contribute to changes in behavior after a normative adult stressor? Alcohol consumption in male Long Evans rats exposed to postnatal maternal separation and adult social defeat stress.

Authors: *B. E. CALDWELL, M. FAIN, K. L. HOCKENBERRY
Ithaca Col., Ithaca, NY

Abstract: The relationship between stress and risk for developing alcohol (ETOH) use disorders has been studied extensively in human and nonhuman animal models. Some rodent models show that stress exposure leads to an increase in preference for ETOH, but this finding is not consistently reported across experimental protocols. The relationship between stress and ETOH drinking is likely modulated by many factors. The nature of the stressor (type, duration, and controllability/predictability), rearing environment, and individual differences in reactivity to ETOH may be important factors in determining whether an organism will develop a heightened preference for ETOH after a stressful event. The present study examined the effects of maternal separation stress during the postnatal period, followed by social defeat stress in adulthood, on ETOH drinking in male Long Evans rats. Newborn litters of Long Evans rats were culled to 6 pups per litter the day of parturition. Litters were randomly assigned to either maternal separation (MS) or animal facility rearing (AFR). The day after parturition (PND1), MS litters were separated from the dam for 180 minutes per day for 14 days. All pups were weaned on PND21. Once mature (at least 60D old), rats were randomly assigned to either defeat stress (DS) or non-stress (NS) control groups. DS animals were exposed to five daily 5-minute defeat sessions. Finally, rats were tested for ETOH preference using a three-bottle choice protocol (10% ETOH/.5% saccharin; 5% ETOH/.5% saccharin consumption; .5% saccharin only). Preliminary results show animals exposed to both MS and DS preferred the 10% ETOH solution over the 5% and drank more (measured in g/kg) ETOH on average than AFR/NS animals. Pilot data obtained to date do not suggest a difference between NS rats and those exposed to DS only, and show a marginal difference between MS/DS and MS/NS animals. In addition to the alcohol drinking protocol, individual differences in sensitivity to ETOH were determined by a single administration of 1.5 g/kg ETOH, injected IP, followed by a test for motor coordination/ataxia using an automated “rotarod” (Med Associates) and observation in an open field to measure locomotor activity. Future analyses are planned for examining the correlation between initial response/sensitivity to ETOH (ataxia and locomotor behavior) and the amount of ETOH consumed following defeat stress. Finally, pharmacological targeting of dorsal raphe CRF is

under way in order to examine whether stress-related alcohol preference is determined by HPA axis activity surrounding the defeat experience.

Title: Differential effects of d1 and d2 receptors in the perifornical lateral hypothalamus in controlling ethanol drinking: possible interaction with orexin neurons

Authors: *Y.-W. CHEN[1,2], I. MORGANSTERN[2], J. R. BARSON[2], B. G. HOEBEL[1], S. F. LEIBOWITZ[2]
[1]Dept. of Psychology, Princeton Univ., Princeton, NJ; [2]Lab. of Behavioral Neurobiology, The Rockefeller Univ., New York City, NY

Abstract: The neurotransmitter, dopamine (DA), is known to promote motivated behaviors, such as ethanol drinking, by acting in various mesolimbic brain regions. Indirect evidence from feeding and electrophysiological studies suggests, however, that the DA system in the perifornical lateral hypothalamus (PFLH), where both DA1 (D1) and DA2 (D2) receptor subtypes exist, has different functions in controlling ethanol consumption. In addition, these functions may be a consequence of DA acting on local neurons expressing the orexigenic peptides, orexin/hypocretin (OX) or melanin-concentrating hormone (MCH). The present study therefore tested the specific hypothesis that activation of the D1 receptor in the PFLH increases the consumption of ethanol, possibly by stimulating local peptide neurons, whereas activation of the D2 receptor in this region produces the opposite behavioral and neurochemical effects. In Experiments 1-2, adult, male Sprague-Dawley rats, trained to drink 7% ethanol, were microinjected in the PFLH with a D1 receptor agonist (SKF81297; 5.4, 10.8 nmol) or antagonist (SCH23390; 8.7, 17.4 nmol) or a D2 receptor agonist (quinelorane; 3.1, 6.2 nmol) or antagonist (sulpiride; 11.7, 23.4 nmol), with measurements of ethanol, chow, and water intake taken for 4 hours after injection. In Experiments 3-4, the effect of PFLH injection of the receptor agonists, SKF81297 and quinelorane, on local expression of OX and MCH was measured using both

radiolabeled *in situ* hybridization (ISH) and digoxigenin-labeled ISH. Results showed that PFLH injection of SKF81297 significantly stimulated ethanol intake but had no effect on chow or water intake. This is in contrast to the D2 agonist quinelorane, which caused a specific suppression of ethanol consumption. Injections of their antagonists into the PFLH produced opposite effects from the agonists, suggesting that both D1 and D2 receptors are tonically active in this brain area in controlling ethanol intake. In addition to their opposite effects on ethanol drinking, PFLH injection of SKF81297 and quinelorane had differential effects on OX mRNA expression. The former compound increased OX expression, while the latter reduced it, with both effects occurring specifically in the LH subregion. In contrast to OX, the expression of MCH was largely unaltered by these D1 and D2 agonists. These results show that DA in the PFLH, by acting on distinct receptor subtypes, may differentially control ethanol consumption by interacting locally specifically with OX neurons.

Title: Strain and sex dependent effects on the severity of ethanol-induced brain damage

Authors: S. LATTIMER[1], A. J. ELBERGER[1], L. LU[1], *K. M. HAMRE[2]
[1]Dept. of Anat. & Neurobiol., Univ. Tenn. Hlth. Sci. Ctr., Memphis, TN; [2]Univ. Tennessee Hlth. Sci. Ctr., MEMPHIS, TN

Abstract: Chronic ethanol exposure has been shown to cause significant damage to the CNS. Recent evidence has suggested that the genetic background and/ or sex of the individual may impact the level of damage observed. However, little is known about whether these variables are critical or whether there is an interaction between the two variables that alters the level of CNS

damage following chronic ethanol exposure. To begin to address whether sex, strain or their interaction impacts ethanol-induced cell damage, male and female mice from four different BXD strains and the C57/BL6J (B6) parental strain were examined. Cell damage was assessed by evaluating changes in expression levels of 3 markers: 1) the astrocytic marker GFAP to assess whether there was an astroglial response, 2) the dendritic marker MAP2 to assess changes in neuronal processes, and 3) the inflammatory marker TLR-4 to assess inflammatory changes. Mice were treated through gavage for ten days with 5 g/kg of ethanol or isovolumetric saline following the protocol of Qin et al. (J. Neuroinflammation 5:10, 2008). Messenger RNA was isolated from the forebrain of each mouse. Expression levels in ethanol-treated or saline-treated control mice were determined through qRT-PCR. Control values were computed for each strain and each sex within a strain, and changes from controls were determined for each ethanol-exposed animal in each strain and sex. The analyses demonstrated that each marker showed different sensitivities among the strains. These experiments revealed significant effects of strain in the analysis of MAP2 and significant effects of sex within the B6 strain in the analysis of GFAP expression. Moreover, even with this limited strain analysis, we have identified one strain, BXD 73, that showed large effects on all measures, suggesting it to be highly sensitive to ethanol-induced brain damage. These data suggest that genetics and sex are critical variables in determining the level of damage observed in the CNS following chronic ethanol exposure. Additional studies are needed to further test the role of these variables and to identify the genetic networks that underlie these differences.

Title: Excessive ethanol consumption disrupts the protective function of BDNF signaling within the dorsolateral striatum.

Authors: *E. DARCQ, V. WARNAULT, J. JEANBLANC, D. RON
Ernest Gallo Res. Ctr., EMERYVILLE, CA

Abstract: The brain-derived neurotrophic factor (BDNF) plays an important role in neuronal proliferation, differentiation and survival, as well as synaptic plasticity [1]. BDNF binds and activates the high affinity TrkB receptor as well as the low affinity p75 neurotrophin receptor (p75-NTR) which can negatively modulate TrkB signaling [2]. Previously, we reported that the expression of BDNF in the dorsolateral striatum (DLS) of rats is induced in response to moderate self-administration of ethanol [3]. We further found that the activation of the BDNF receptor TrkB in the DLS of rats attenuates operant self-administration of moderate levels of ethanol, whereas siRNA-mediated knockdown of BDNF expression in the DLS increases self-administration of moderate levels of ethanol [3]. Together, these results suggest that the BDNF/TrkB-mediated signaling pathway in the DLS is part of a homeostatic pathway that gates the level of moderate ethanol intake [3-4]. Next, we hypothesized that excessive ethanol intake results in the breakdown of the protective actions of BDNF. To test this hypothesis, rats with a history of high levels of ethanol intake (20%v/v, 2-bottle choice) were trained to self-administer 20% ethanol in an operant self-administration paradigm. We then tested whether manipulations of BDNF levels still affect ethanol self-administration. We found that under these conditions, knockdown of BDNF levels or activation of the BDNF pathway in the DLS ceases to alter ethanol intake, suggesting that the transition from moderate to excessive ethanol drinking results in a breakdown of the BDNF pathway. Activation of p75-NTR produces responses that are opposite to those of TrkB [2]. We hypothesized that a history of excessive drinking alters p75-NTR expression and/or neuronal localization. We found that the synaptic localization of p75-NTR is increased only in the DLS of rats with a history of excessive ethanol drinking after 24 hrs of withdrawal, but not after moderate ethanol intake. Together, our results suggest that excessive ethanol drinking disrupts the protective BDNF signaling by changing p75-NTR localization.

Title: Diving deeper into zebrafish shoaling data: A focus on embryonic alcohol exposure effects

Authors: *C. BUSKE[1], R. T. GERLAI[2]
[1]Univ. Toronto, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: The mechanisms and development of vertebrate social behavior are not fully understood. Numerous human clinical conditions exist in which abnormal social behavior is part of the symptoms, among these are alcoholism and fetal alcohol syndrome. Animal models may facilitate the understanding of the mechanisms of social behavior and the mechanisms underlying abnormal social behavior.

We investigated how single zebrafish move in an open field and quantified swim speed and thigmotaxis. We also investigated zebrafish shoaling (group forming) in the open field by quantifying shoal cohesion in groups of ten fish. In the latter experiment, we studied how embryonic alcohol exposure affected the ontogenesis of shoaling. Although a large body of literature exists on the effects of fetal alcohol exposure, many studies have been completed using unrealistically high alcohol concentrations. To make our investigation more easily extrapolated to clinical circumstances, we employed low doses of alcohol and a short exposure time (2 hours) at 24 hours post-fertilization. A previous study has demonstrated this dosing regiment to be sufficient to cause significant reduction in social preference when measured in adult fish (Fernandes & Gerlai, 2009).

Preliminary results have suggested that embryonic alcohol exposure decreases shoal cohesion in maturing (>40dpf aged) and adult (90dpf) zebrafish. The current study expands on these findings by analyzing shoal cohesion for a larger sample size (n=10), and at smaller time intervals (15 different age points during development). Previous studies from our research group have also shown an oscillating pattern in shoal cohesion of zebrafish (Miller & Gerlai, 2008), here we study whether these oscillating patterns are affected by embryonic alcohol exposure. Miller & Gerlai also reported a change in shoaling oscillations when a stimulus like a predator or food was presented. Additional work published previously has shown that embryonic alcohol exposure lowers Dopamine, DOPAC, Serotonin, and 5-HIAA levels in the brain, throughout development and in the adult (Buske & Gerlai, 2011). These neurochemicals are implicated in various behaviours, with Dopamine also playing a role in social behaviour. Measuring changes in shoaling behaviour following the same treatment that lead to neurochemical changes in previous work serves as a starting point of improving our understanding of the underlying mechanisms affected by embryonic alcohol exposure.

Title: Effect of chronic intermittent ethanol exposure on extracellular glutamate levels and uptake in nucleus accumbens in C57BL/6J mice

Authors: *V. S. RAMACHANDRA, L. A. KNACKSTEDT, W. C. GRIFFIN, 3rd, C. L. HAZELBAKER, H. L. HAUN, L. SNYDER, H. BECKER
Med. Univ. of South Carolina, Charleston, SC

Abstract: Previous studies using a mouse model of ethanol dependence and conventional microdialysis procedures have demonstrated that repeated cycles of chronic intermittent ethanol (CIE) exposure increased baseline extracellular glutamate levels in the nucleus accumbens (NAc). Elevated glutamate tone in the NAc was observed beyond acute withdrawal (1-2 weeks following CIE exposure) and was associated with increased ethanol drinking. However, the source of elevated glutamate levels in NAc is currently unknown. This study tested the hypothesis that CIE exposure produces elevated basal glutamate levels by decreasing glutamate re-uptake via excitatory amino acid transporters (EAATs) and/or increasing glutamate release via system xc-. Adult male C57BL/6J mice received repeated cycles of CIE vapor exposure (16 hr/day, 4 days/week to achieve BECs 175 - 225 mg/dL) every other week. Using quantitative microdialysis procedures, we confirmed that CIE-exposed mice showed significant elevation (nearly 2-fold increase) in basal accumbal glutamate levels compared to air-exposed controls. In separate groups of mice, an ex-vivo glutamate uptake assay was used to measure both glutamate uptake (via EAATs) and export (via system xc-) in the NAc at 72-hr following the 4th cycle of CIE exposure. [3]H-glutamate was measured in tissue samples in the presence and absence of sodium to assess sodium-dependent (EAATs) and sodium-independent (system xc-) transporter function, respectively. Results indicated no significant differences in NAc glutamate uptake or export between CIE-exposed and control mice. Studies are currently underway to examine other potential sources of glutamate release, such as neuronal hyperexcitability as possibly contributing to the increased accumbal extracellular glutamate levels observed in ethanol dependent (CIE-exposed) mice.

Title: Ethanol increases KLF11 (TIEG2) promoter activity in SH-SY5Y cells

Authors: *S. L. SWILLEY[1], S. JOHNSON[1], C. UDEMGBA[1], P. R. ALBERT[2], J. LUO[3], *D. SITTMAN[1], *X.-M. OU[1]
[1]Dept Psychiatry and Human Behavior, Univ. MS Med. Ctr., JACKSON, MS; [2]Neurosci., Ottawa Hosp. Res. Inst., Ottawa, ON, Canada; [3]Univ. of Kentucky Col. of Med., Lexington, KY

Abstract: Alcohol abuse results in brain damage and one possible mechanism is through its activation of the enzyme monoamine oxidase B (MAO B). The catalytic activity of MAO B generates reactive oxygen species and oxidative stress and ethanol-induced increases in MAO B activity likely contribute to ethanol's neurotoxicity. Although the molecular mechanisms involved in ethanol-induced MAO B activation have not been fully elucidated, our laboratory has shown that the TGF-β inducible early gene transcription factor, transforming growth factor beta-inducible early gene 2 (TIEG2, also known as Kruppel-like factor 11, KLF11) is involved in the process. KLF11 (TIEG2) has been found to inhibit cell growth, induce apoptosis, and increase the expression of MAO B. Moreover, our studies have shown that ethanol exposure increases the gene expression of KLF11, with KLF11 leading to further increases in ethanol-induced MAO B expression. The human KLF11 promoter contains DNA elements previously reported to be responsive to ethanol and/or oxidative stress. Therefore, the purpose of the present study was to determine whether the KLF11 promoter could be activated upon ethanol exposure.
The KLF11 1.5 kb promoter was generated and fused in frame to the pGL4 luciferase reporter gene vector (Promega). Human neuroblastoma SH-SY5Y cells were co-transfected with the KLF11 promoter-luciferase gene construct and the pRL-TK plasmid (renilla luciferase expression vector used as an internal control) using the superfect transfection reagent (Qiagen). The transfected cells were subsequently treated with ethanol (75 mM, 24 hr) in a closed chamber system. Following the exposure period, the cells were harvested and luciferase activity was determined.

There was a significant increase in the KLF11 1.5 kb promoter activity of the transfected cells treated with ethanol compared to untreated controls (Controls: 9.58±0.412 vs Ethanol-treated: 12.29±1.95, $p < 0.05$), suggesting that ethanol activates the KLF11 promoter. Because ethanol may activate the promoter through other transcription factor(s), future studies will determine the proteins and DNA interacting elements that are responsible for the effects of ethanol exposure. Our present and future studies will expand our understanding of the molecular mechanisms involved in ethanol-induced KLF11 (TIEG2) activation as well as provide further insight in to the mechanisms by which ethanol leads to brain cell damage.

Title: Chronic ethanol intake increases immunohistochemical expression of Kruppel-like factor 11, a transcriptional activator of monoamine oxidase B, in the prefrontal cortex of rats

Authors: J. W. DUNCAN[1], C. A. STOCKMEIER[1], J. WANG[1], J. LUO[2], S. JOHNSON[1], *W. L. WOOLVERTON[3], X.-M. OU[1]
[1]Psychiatry and Human Behavior, Univ. of Mississippi Med. Ctr., Jackson, MS; [2]Col. of Med., Univ. of Kentucky, Lexington, KY; [3]Psychiatry, Univ. Mississippi Med. Ctr., JACKSON, MS

Abstract: Alcoholism is a substance dependence disorder that affects daily responsibilities, physical health, memory, and neuropsychological fitness and may represent an acquired insult to the brain. Neuronal atrophy occurs in subjects with alcohol dependence, as seen with reduced prefrontal cortex (PFC) volume and decreased densities of neuronal and glial cells in human postmortem studies. One cause of cell death may be the Kruppel-like factor (KLF) 11 (also referred to as transforming growth factor-beta-inducible early gene 2, TIEG2)-mediated signaling pathway that is activated during ethanol exposure. Previous reports indicate that glyceraldehyde-3-phosphate dehydrogenase (GAPDH), a multifunctional protein also involved in transcriptional regulation, can translocate to the nucleus in the presence of ethanol, augment

KLF11 and increase monoamine oxidase (MAO) B transcription *in vitro*. An increase in MAO B-mediated oxidative stress results in neuronal atrophy due to the formation of hydrogen peroxide, a byproduct of MAO B metabolism. Therefore, the GAPDH-KLF11-MAO B cell death cascade may be a novel mechanism promoting ethanol-induced neuronal death in alcoholism. We examined whether immunohistochemical expression of KLF11 protein would be increased in the PFC of rats chronically exposed to ethanol (N=10), as compared to ethanol-preferring controls (N=10). The dose of ethanol was physiologically comparable to that in humans. We examined the medial prefrontal cortex (mPFC) and the pre-motor frontal cortex. Rats were fed an isocaloric quantity of ethanol or glucose liquid control diet for 28 days, after which brains were removed and sectioned coronally. Unbiased 3-dimensional cell counting revealed a significant increase in the density of KLF11-immunoreactive cells in both the mPFC and frontal cortex by 36% and 28%, respectively, when compared to ethanol-preferring controls. These results indicate that chronic ethanol exposure in rats increases the recruitment of KLF11 which may enhance downstream expression of MAO B, resulting in excessive neurotransmitter metabolism and consequently, increased oxidative cellular stress. Enhanced KLF11 (TIEG2) expression in prefrontal cortex may critically affect learning, memory and autonomic responses regulated in this region.

Title: Effects of insular cortex inactivation on chemosensory responsiveness to ethanol

Authors: N. CASTRO, E. DRIVER, J. DUDLEY, J. GODFREY, B. FERETIC, C. QUINTANILLA, *S. M. BRASSER
San Diego State Univ., SAN DIEGO, CA

Abstract: Recent findings indicate that the insular cortex (i.e., limbic sensory cortex) is critically involved in addictive behavior to multiple drugs of abuse by regulating an organism's responsiveness to drug-associated sensory cues that trigger craving or "urge to use" (Naqvi & Bechara, 2009). Damage sustained to the insula in addicted smokers results in a disruption of

nicotine addiction (Naqvi et al., 2007) and pharmacological inactivation of the insula in rodents disrupts conditioned preference for environments previously paired with amphetamine or nicotine (Contreras et al., 2007; Scott & Hiroi, 2011) and prevents or suppresses cue-induced reinstatement of nicotine- and cocaine-seeking (Forget et al., 2010; DiPietro et al., 2006). Human imaging studies have demonstrated activation in the insula during the experience of drug-related craving and exposure to drug-associated cues (Bonson et al., 2002; Brody et al., 2002; Wang et al., 1999, 2007), including the taste of alcohol in heavy drinkers (Filbey et al., 2008). The present study measured chemosensory responsiveness to ethanol in chronically ethanol-exposed or naive rats under conditions of pharmacological "silencing" of the caudal granular/dysgranular insular cortex to directly examine the role of this brain region in mediating responses to ethanol-associated sensory cues. Outbred Wistar rats were initially exposed for five weeks to either a 20% ethanol intermittent access paradigm or were given access only to water. Following implantation of intracranial cannulae, rats from each exposure condition were subsequently tested over five consecutive days for short-term lick responses to ethanol (3-40%) and a water control after receiving bilateral insula infusions of saline or muscimol. Alcohol-experienced rats displayed a concentration-dependent increase in chemosensory avidity for ethanol compared to alcohol-naive rats, evidenced by elevated lick responses and trial sampling frequency particularly at higher ethanol concentrations (15-40%). Inactivation of the insula eliminated this concentration-dependent response in chronically exposed animals, with total licks to ethanol and water not differing, which was driven primarily by a decrease in number of ethanol trials sampled. Insula inactivation did not modify orosensory responses to ethanol in alcohol-naive animals. These data support insular cortex involvement in mediating responsiveness to conditioned alcohol chemosensory cues following chronic association of ethanol's taste and post-absorptive effects.

Title: Pharmacological enhancement of extinction learning attenuates alcohol-seeking behavior and alters neuronal plasticity within the addiction neurocircuitry.

Authors: *J. T. GASS, A. S. KASSAB, K. B. LOGOTHETIS, L. J. CHANDLER
Med. Univ. South Carolina, CHARLESTON, SC

Abstract: Extinction-based cue exposure therapies have proven ineffective in the treatment of alcoholism. Our lab has shown that positive allosteric modulation of mGluR5 with CDPPB can enhance the extinction learning of alcohol cues in rats. The current study was designed to assess changes in neuronal plasticity in specific brain regions that correlate with facilitated extinction learning and examine the impact of CDPPB treatment on relapse-like behavior. Male Wistar rats were trained to self-administer a 10% alcohol solution. Active lever presses were accompanied by a light/tone complex stimulus. Rats were then exposed to an extinction training or forced abstinence procedure and were given either an injection of CDPPB (30 mg/kg s.c.) or vehicle (10% Tween 80) 20 minutes prior to each session. Lever pressing behavior was monitored until extinction criteria were met. A diolistic-labeling technique combined with 3D image analysis was used to assess changes in dendritic spines in areas of the prelimbic (PrL) and infralimbic (IfL) subregions of the prefrontal cortex (PFC) and nucleus accumbens (NAc) after extinction learning. To investigate the impact of CDPPB treatment on relapse-like behavior, a separate group of rats was treated with CDPPB during extinction training and subsequently exposed to a cue-induced or contextual-reinstatement session. Treatment with CDPPB during extinction training facilitated extinction learning and resulted in a significant attenuation of cue-induced alcohol-seeking behavior, suggesting that this compound can reduce the impact of alcohol-associated cues on drug-seeking behavior. Additionally, extinction learning was associated with a significant increase in total spine density in the IfL-PFC. Importantly, this effect was promoted in animals that displayed facilitated extinction learning. Further analysis according to spine type revealed that this increase in spine density was primarily associated with an increase in mature “mushroom” shaped spines. These data are consistent with studies that implicate the IfL-PFC in extinction learning and suggest that positive allosteric modulation of mGluR5 may facilitate the formation of extinction memory traces in this region to increase the efficacy of cue exposure therapy.

Title: Chronic alcohol exposure disrupts cognitive function and D2/D4 receptor modulation of prefrontal cortical function.

Authors: *H. TRANTHAM-DAVIDSON, S. W. CENTANNI, L. J. CHANDLER
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: The medial prefrontal cortex (mPFC) plays a critical role in decision-making and cognitive control of behavior, and these functions are highly influenced by dopaminergic (DA) activity in the mPFC. Previous studies in humans have reported disruption of cognitive processes following repeated episodes of excessive alcohol consumption and withdrawal, suggesting a possible link to altered mPFC function and DA activity in the mPFC. Recurrent network activity between excitatory pyramidal neurons is shaped by recruitment of inhibitory GABAergic neurons, specifically those that are characterized as fast-spiking interneurons (FSIN's). Dopaminergic inputs to mPFC exert powerful effects on network activity via D1/D2 receptor modulation of the balance between excitatory and inhibitory tone. Behavioral assessment of cognitive function revealed delay-dependent impairment of working memory performance in CIE rats compared to controls. These deficits were also associated with a reduction in cognitively modulated increase in phase association of the activity of mPFC neurons to the hippocampal theta rhythm during the epoch of the task that required the rat to use working memory to guide decision-making. In acute slices obtained from both control and CIE animals, D1 stimulation (SKF38393; 5 uM) increased the firing rate of both FS-interneurons and pyramidal neurons indicating that CIE did not alter D1 receptor modulation of cortical activity. However, in slices from CIE animals, the effects of both D2 and D4 stimulation were lost in both cell types. While the cellular mechanisms that underlie the loss of D2/D4 modulation of cortical activity following CIE are unclear and are currently under investigation, our preliminary analysis of spike characteristics and synaptic responses suggests that CIE primarily disrupts D2 signaling in pyramidal neurons and preferentially affects D4 signaling in FSIN's. These changes in D2/D4 receptor function will likely significantly impact DA modulation of PFC activity and may contribute to the cognitive dysfunction associated with CIE exposure. This is consistent with observations in detoxified alcoholics of altered D2 receptor signaling. We suggest that loss of D2/D4 receptor modulation following CIE exposure may shift the cortical network into a D1-

receptor dominated state that may contribute to cognitive deficits observed in human alcoholics. Preliminary experiments suggest that mGluR1 stimulation of FSIN's could be used as a novel therapeutic strategy that will restore the excitatory-inhibitory balance required for network synchrony that supports cognitive function.

Title: Kappa-opioid receptor agonist-induced enhancement of 22-kHz ultrasonic vocalizations is indicative of a negative affective state

Authors: *A. WILLIAMS, B. M. WALKER
Washington State Univ., Pullman, WA

Abstract: Alcohol Use Disorders, comprised of alcohol abuse and alcohol dependence, are a severe problem in the United States. High levels of comorbidity exist between alcohol dependence and negative affective disorders such as anxiety and depression during withdrawal. Alcohol-dependent individuals "self-medicate" by consuming alcohol to reduce the negative affective symptoms of withdrawal, which promotes excessive alcohol consumption. Given that there are no FDA-approved treatments for comorbid alcohol dependence and negative affect, it is important to understand the neurobiological mechanisms of dependence and withdrawal. Dynorphin (DYN), the endogenous ligand for kappa-opioid receptors (KORs), is increased in motivational and affective areas of the rat brain by alcohol dependence and has been shown to regulate excessive alcohol self-administration during acute withdrawal in dependent rats. Measurement of 22-kHz ultrasonic vocalizations (USVs) is an ethologically valid strategy that can be used to assess negative affective-like states in rats. During acute withdrawal, alcohol-dependent rats with escalated patterns of alcohol self-administration also display an increased number and duration of 22-kHz USVs when compared to non-dependent rats. The goal of this study was to mimic an alcohol withdrawal-like state in rats via intracerebroventricular (ICV) infusions of the KOR-agonist U50,488 and assess negative affective-like behavior by measuring

induced 22-kHz USVs. Male Wistar rats received an ICV infusion of one of four doses of U50,488 (0.0, 0.25, 2.5 or 25 µg) 15-min prior to the measurement of induced 22-kHz USVs. U50,488 dose-dependently increased 22-kHz USVs. To assess whether this effect was KOR-dependent, a separate group of rats were treated with the KOR-antagonist nor-BNI 24-hours prior to being infused with U50,488 (25 µg only), and USVs were assessed under the same conditions. Nor-BNI reversed the U50,488-induced increases in USVs. These results demonstrate that activation of KORs is sufficient to induce 22-kHz USVs and support the concept that DYN / KOR systems play an important role in the pathogenesis of alcohol withdrawal-induced negative affective-like states. Collectively, these results add to the field's understanding of the neurobiological mechanisms underlying alcohol dependence and provide an alternative strategy for the characterization of negative affective-like states during withdrawal.

Title: Exercise neurorestoration after repeated binge alcohol exposure

Authors: *M. E. MAYNARD[1], T. J. RASHAUD[1], A. FONSECA[1], J. L. LEASURE[1,2]
[1]Psychology, [2]Biol. & Biochem., Univ. of Houston, Houston, TX

Abstract: This study assessed long-term neural consequences of repeated binge alcohol exposure and potential neurorestorative effects of exercise. Rodent models show that binge alcohol exposure damages the brain, particularly the hippocampus, where it kills cells and inhibits neurogenesis. We have previously shown that exercise protects vulnerable brain regions from subsequent binge alcohol exposure. The present study investigated whether exercise could help restore the brain after binge-induced damage has already occurred. Adult female Long-Evans rats underwent 0, 1 or 2 binge episodes. Rats in the 1 or 2 binge groups were gavaged with ethanol (25% w/v) in nutritionally complete diet every 8 hours for 4 days. Control animals (the 0 binge groups) received isocaloric control diet. Recent evidence from a rodent model suggests that the hippocampus is undergoing self-repair during the first week following a single binge, so

we timed the second binge to begin on day 6 of abstinence, in order to disrupt ongoing neurorestoration. Animals in the exercise groups had access to running wheels 5.5 hours per day, for 28 days, beginning 7 days after their final binge. Rats were sacrificed 35 days after the end of the final binge. Compared to rats that underwent 1 binge, 2-binge animals took longer to reach peak intoxication levels, and withdrawal symptoms were more severe. For all binge groups, there was a positive correlation between behavioral intoxication and severity of withdrawal symptoms. Prior binge alcohol exposure had no effect on distance run. Stereological analysis of dentate gyrus cells positive for doublecortin (DCX, an early neuronal marker) revealed no effect of a single binge, but a second binge significantly reduced the number of DCX+ cells. As has been previously shown, exercise increased the number of DCX+ cells in control animals. However, there was no increase in DCX+ cells in exercising single binge animals, indicating a binge-induced suppression of the neurogenic effect of exercise. The effect of exercise after repeated binge episodes on cell proliferation and granule cell survival after 35 days, and the effect on DCX+ positive cells after a second binge, are currently being investigated. We conclude that repeated binge alcohol exposure causes a lasting suppression of neuronal differentiation in the hippocampus, and that exercise, which promotes neurogenesis in the alcohol-naïve brain, may have limited ability to do so in the binge-exposed brain.

Title: Autobiographical memory and social cognition in youth with Fetal Alcohol Spectrum Disorder.

Authors: *S. AGNIHOTRI[1], J. ROVET[3], G. KOREN[3], C. RASMUSSEN[4], D. CAMERON[2], J. RYAN[2], M. KEIGHTLEY[2]
[1]Grad. Dept of Rehabil. Sci., [2]Univ. of Toronto, Toronto, ON, Canada; [3]Hosp. for Sick Children, Toronto, ON, Canada; [4]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Background: Adolescents with Fetal Alcohol Spectrum Disorder (FASD) often demonstrate deficits in social cognition and emotion processing, which negatively impact the

development of appropriate social skills. Consequently, they can experience social and community withdrawal and display an increased likelihood of remaining socially isolated in adulthood. Autobiographical memory (AM) has been found to be critical for the development of appropriate social behaviors; however, it has not been determined whether AM is impaired in children and adolescents with FASD and if this contributes to inadequate social skill development and social withdrawal found with these youth.
Specific Objectives: The specific objectives of the study are to: (1) compare AM recall performance between adolescents living with a diagnosis of FASD and a group of control participants without an FASD-diagnosis and; 2) determine whether AM recall can predict performance on tasks designed to measure social cognition (i.e. theory of mind and emotion processing).
Methods: Participants were 45 adolescents with FASD and 45 control participants aged 13-17 years. The groups were compared on the number of internal and external AM details that were recalled using the Children's Autobiographical Memory Interview, as well as scores on the Everyday Memory Questionnaire. Social cognition was compared using clinical and experimental measures of emotion processing and theory of mind. Regression analyses were used to understand whether AM can predict social cognitive performance.
Results: Marked deficits in AM performance, poor performance on tests of theory of mind and emotion processing and deficits in AM performance predicting social cognitive impairments is suggested.
Significance: This study is the first to our knowledge that has investigated AM in youth with FASD and lays the groundwork for future neuroimaging research to better clarify the negative impacts of prenatal alcohol exposure on AM development. A better understanding of the function of AM throughout adolescence in these youth will also increase our knowledge of the underlying mechanisms that may be related to the development of mental health problems faced by these youth.

Title: Neuronal nicotinic receptor ligands modulate chronic ethanol-induced ΔFosB up-regulation in mouse striatum

Authors: *S. RAHMAN, R. K. SAJJA
Pharmaceut. Sci., South Dakota State Univ., BROOKINGS, SD

Abstract: Chronic exposure to drugs of abuse including alcohol (ethanol) induces persistent accumulation of ΔFosB, a unique transcription factor that regulates long lasting neuronal adaptations, in the brain reward system. Recently, we have demonstrated that neuronal nicotinic acetylcholine receptor (nAChR) ligands such as cytisine attenuate binge-like ethanol drinking and preference in mice. Here, we examined the effects of cytisine (partial agonist at α4β2* nAChR subtype) and mecamylamine (non-selective nAChR antagonist), on chronic ethanol-induced striatal expression of ΔFosB in male C57BL/6J mice. Following exposure to free-choice 24-h ethanol (15% v/v) and water drinking for 25 days, animals (n=5/group) received intraperitoneal injections of saline, cytisine (0.5 mg/kg) or mecamylamine (3 mg/kg) on six consecutive days (once-a-day prior to fluid access). After 18-24 h from the termination of ethanol access, mice were sacrificed and ΔFosB expression in dorsal and ventral striatum was determined by western blot analysis. Cytisine or mecamylamine significantly suppressed 24-h average ethanol intake (56 ± 4.5% or 63 ± 6.7% of saline, respectively), following the third day of treatment. Consistent with the behavioral data, cytisine significantly reduced (116 ± 11% or 114 ± 13% of water control) chronic ethanol-induced expression of ΔFosB (194 ± 14% or 203 ± 24% of water control) in dorsal and ventral striatum respectively, while the reducing effects of mecamylamine were modest (146 ± 23% and 143 ± 18% of water control). Overall, these results indicate that nAChR ligands modulate the up-regulation of striatal ΔFosB following chronic voluntary ethanol consumption in mice. Thus, this study provides further evidence for the role of nAChRs in neurobiology of alcohol addiction. (*Supported in part by SDSURF-JRF grant)*

Title: Putative NMDA receptor hypofunction contributes to impaired contextual memory consolidation in a rodent model of fetal alcohol syndrome

Authors: *M. J. GOODFELLOW, D. H. LINDQUIST
Behavioral Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Fetal alcohol spectrum disorders (FASD) encompass a constellation of physical and mental abnormalities that may arise from prenatal alcohol exposure. In the present study, a rat model of fetal alcohol syndrome (FAS) is employed to investigate the effects of postnatal day (PD) 4-9 ethanol exposure, a period equivalent to the human third trimester. Perinatal exposure induces neuronal loss in the hippocampus (Gil-Mohapel et al., 2010; Livy et al., 2003), as well as deficiencies in hippocampal-dependent contextual fear conditioning (Murawski & Stanton, 2010). Such exposure is also reported to alter normal developmental changes in forebrain NMDA receptor (NMDAR) subunit composition and expression (Samudio-Ruiz et al., 2010). We hypothesize that ethanol exposure early in development dysregulates NMDAR function, which may contribute to impaired contextual fear learning, acquisition of which relies on NMDAR-dependent synaptic plasticity within the dorsal hippocampus (Matus-Amat et al., 2007). Indeed, 5 minutes of simple context exposure dramatically increases expression of activity-regulated cytoskeleton-associated protein (Arc/Arg3.1), a proposed biomarker of NMDAR activity involved in the maintenance of LTP (Ramirez-Amaya et al., 2005). The current study aims to relate NMDAR activity in FAS rats, as revealed by Arc protein expression, and hippocampal-dependent learning, based on the context pre-exposure facilitation effect (CPFE). In this task, pre-exposure to a specific context in phase 1 facilitates its subsequent association with an immediate footshock in phase 2, resulting in enhanced freezing rates during phase 3 retention testing (Fanselow, 2000; Rudy & O'Reilly 2001). In an attempt to identify the stage of learning in which FAS rats are compromised (encoding, consolidation, or retrieval), two different intervals separating the context pre-exposure and immediate shock are employed- 2 or 24 h. The former relies on a short-term memory of the contextual representation which can be associated with the shock independent of consolidation, whereas the standard 24 h interval requires memory consolidation for successful learning. Preliminary data indicates adult FAS rats are impaired with the 24 h, but not the 2 h, exposure-to-shock interval. Separately, Western blot protein analyses prepared from the dorsal hippocampus 1 h after context exposure (phase 1) provisionally suggest that Arc expression may be reduced in FAS rats. Taken together, we propose that FAS rats are capable of encoding the contextual representation but may be specifically impaired in its consolidation, possibly due to ethanol-induced NMDAR hypofunction.

Title: Long-term changes in cortical excitability following a single binge ethanol exposure.

Authors: *J. ZIBURKUS[1], F. GU[1], M. MAYNARD[2], A. AULAKH[1], J. L. LEASURE[2]
[1]Dept Biol & Biochem, [2]Dept of Psychology, Univ. Houston, HOUSTON, TX

Abstract: Recent evidence suggests that a single binge exposure may have long-lasting effects on brain areas vulnerable to ethanol, including the hippocampus and frontal cortex. In the present study, we investigated neural network changes in these regions 35 days after a single 4-day binge ethanol exposure. Adult female Long-Evans rats were gavaged with ethanol (25% w/v) in nutritionally complete diet every 8 hours for 4 days. Control animals received isocaloric control diet. Five weeks later, network activity was studied using electrophysiology and fast voltage-sensitive dye imaging (VSDI) in vitro. Studies were performed in the hippocampus areas CA1 and dentate gyrus and in the prefrontal cortex, layers II-III. The strongest effect of binge drinking on neural network activity was observed in the neocortical slices. Intracortical activity was probed using single pulse, paired-pulse and train stimulations in the gamma range frequency (40Hz). In the binged animals, stimulations of layer IV evoked abnormally large field potential responses in the superficial layers II-III. Measurements of evoked responses during the ten pulse train stimulation revealed subtle changes in the intracortical synaptic short-term plasticity (STP). On average, in binged animals evoked neocortical field potential responses were depressing, while they were facilitating in the control animals. VSDI performed concurrently with extracellular electrophysiology showed that layer IV stimulation evoked spatially wider activity maps in the binged animals, suggesting reduced specificity in the spatial neocortical network activation and aberrant excitability. Taken together, our results suggest that five weeks following a single binge ethanol exposure, the neocortical network activity and synaptic STP are altered. Further ongoing investigations are characterizing if the subtle changes in neural circuit activity seen at five weeks following single binge ethanol exposure are time-dependent and more pronounced at earlier times after the binge.

Title: CrebA and acquired drug tolerance in *Drosophila*

Authors: *B. TROUTWINE[1], N. ATKINSON[2]
[2]iCMB, [1]Univ. of Texas, Austin, TX

Abstract: We study the mechanisms that underlie the acquisition of tolerance to drugs of abuse using Drosophila as a model. Drug tolerance is defined as to a reduced response to a drug caused by previous drug exposure, and is a core component of addiction. We are attempting to understand how the nervous system changes after drug exposure in order to reduce the effect of a drug upon subsequent exposure. Our lab has previously shown that one such mechanism is the induction of the BK channel gene *slowpoke* after drug exposure. This leads to an increased capacity for repetitive firing, which counters the sedative effect of the drug. Our lab has also shown that the Drosophila CREB homolog *Creb2* plays a role in the regulation of *slowpoke* following sedation and that *CrebA* was induced after sedation, hinting that it may be involved. In this study we seek to establish *CrebA*'s role in the acquisition of tolerance to ethanol.
In this study we use a two day behavioral assay to test for the ability to acquire tolerance to the sedative effects of ethanol. Animals are divided into two groups, and on the first day one group is sedated with ethanol vapor while the other group receives a mock treatment. 24 hours later both groups are exposed to ethanol vapor while movement and climbing are recorded. Wild type flies receiving their second dose of ethanol take longer to sedate than naïve flies.
We show that three alleles that disrupt the *CrebA* locus interfere with the acquisition of tolerance to ethanol. Additionally, induction of a *CrebA* transgene mimics the tolerant state in drug-naïve animals. We are currently investigating whether *CrebA* regulates *slowpoke* following sedation in order to induce the tolerant state.

Title: Sex and age related differences in the impact of binge alcohol drinking on hippocampal mGluR1/5 levels

Authors: *D. K. COZZOLI[1,2], M. N. STRONG[1], M. R. FORQUER-ANDREW[2], K. M. WIREN[1,2], D. A. FINN[1,2,2]
[1]Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR; [2]VA Med. Res., Portland, OR

Abstract: Binge alcohol drinking is a growing health concern, and a history of binge alcohol use is a strong predictor of subsequent alcohol dependence. Previous studies in male rodents indicate that systemic inhibition of metabotropic glutamate receptor 5 (mGluR5) decreases alcohol consumption, including binge drinking, while systemic inhibition of metabotropic glutamate receptor 1 (mGluR1) fails to consistently alter alcohol consumption. Therefore, the present study sought to examine whether binge drinking differentially impacts hippocampal mGluR1 and mGluR5 levels in a sex- and age-dependent manner. C57BL/6J mice (males and females, 8 week old adults and 4 week old adolescents) were single-housed and introduced to the Scheduled High Alcohol Consumption paradigm. In this paradigm the animals receive intermittent (every 3rd day) access to 5% alcohol for 30 minutes, which produces blood alcohol concentrations that average 150mg% and exceed the NIAAA criteria for a binge (80mg%). Following 24-hour withdrawal from the seventh binge session, the hippocampus was dissected, homogenized, and protein levels were analyzed using western blotting. The levels of mGluR1 within the hippocampus were not affected by binge alcohol consumption, and there was no difference between males and females or adults and adolescents. On the other hand, hippocampal mGluR5 levels were altered in a sex-, age-, and treatment-dependent manner. In females, basal mGluR5 levels differed between adults and adolescents, with adolescents having a 40% increase in mGluR5 when compared with adults. However, binge alcohol consumption did not impact mGluR5 levels in either age group. In males, there was an age- and treatment-dependent effect of alcohol consumption, with binge alcohol consumption increasing mGluR5 levels by 42% in adults but decreasing the levels by 15% in adolescents. As mGluR5 lies up-stream of the PI3 kinase signaling cascade, these results suggest that binge alcohol consumption may not only impact the levels of mGluR5 but may also influence the levels and/or phosphorylation of PI3K, PDK1, mTOR, 4EBP1, and p70s6k in a sex- and age-specific manner. This line of investigation is ongoing in the laboratory. Together these data indicate that binge alcohol consumption produces sex- and age-specific alterations in hippocampal mGluR5 levels and suggest that further investigation may elucidate how males and females as well as adults and adolescents may benefit from unique pharmacotherapeutics.

Title: The influence of alcohol on striatal dopamine dynamics in BDNF-deficient mice

Authors: *B. NEWMAN, K. BOSSE, A. APAWU, T. MATHEWS
Chem., Wayne State Univ., Detroit, MI

Abstract: Understanding how the brain reacts and adapts to moderate alcohol intake is a critical step in figuring out what makes some individuals more vulnerable to alcoholism, despite the many detriments associated with the disease. The molecular mechanism that turns a 'casual' drinker into a 'compulsive' drinker is unknown, but it is thought that persistent alcohol consumption induces long-term changes in the reward pathways of the brain at both the cellular and molecular levels. Clinical studies have shown connections between SNPs in the gene-encoding brain-derived neurotrophic factor (BDNF) and vulnerability and relapse in alcoholism. Furthermore alcohol consumption has been shown to be altered through animal studies in which BDNF-signaling is manipulated. The evidence of BDNF's role in alcohol consumption and dependence is substantial, but recently BDNF has also been shown to be a potent modulator of dopamine (DA) neurotransmission. Using knockout mice with a 50% reduction in BDNF protein ($BDNF^{+/-}$) the objective of this research is to understand how genetic manipulations and alcohol consumption influence DA dynamics in the striatum. In this study the drinking-in-the-dark (DID) paradigm was used for 7 days of voluntary ethanol exposure to both wildtype (WT) and $BDNF^{+/-}$ mice. In the drinking behavior alone, significant differences were observed between genotypes, with the WT mice consuming a consistent amount (2.82 g/kg) over 7 days while the $BDNF^{+/-}$ mice showed a two-fold increase in ethanol consumed from day 1 to day 7. Ethanol induced changes in DA levels following 7 days of DID were determined using microdialysis. In naïve animals, ethanol challenge elicited an increase in DA levels and this increase was significantly blunted following DID exposure in both genotypes. Using slice fast scan cyclic voltammetry (FSCV), $BDNF^{+/-}$ mice showed alterations in electrically-stimulated DA release and uptake, whereas the WT mice illustrated no change. Overall the DA dynamics of the $BDNF^{+/-}$ mice seem

to be more heavily affected by 7 days of DID compared to their WT counterparts. In the future, other alterations will be explored further using pharmacological manipulations, as well as further characterization of the DA system such as autoreceptor functionality.

Title: Chronic intermittent alcohol alters dendritic spine morphology and plasticity-related proteins in the mouse prefrontal cortex

Authors: *N. N. NEW[1], S. KROENER[2], J. T. GASS[1], P. J. MULHOLLAND[1], H. C. BECKER[1], L. J. CHANDLER[1]
[1]Neurosciences and Charleston Alcohol Res. Ctr., MUSC, Charleston, SC; [2]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Dallas, TX

Abstract: The medial prefrontal cortex (mPFC) is implicated in complex cognitive operations including impulse control, behavioral plasticity, and motivation. The mPFC is of particular interest in the development and maintenance of addiction due to its role in top-down (e.g., experience-driven) processing. Long-term alcohol consumption is associated with structural abnormalities and neurological deficits attributed to dysfunction of the PFC. A recent study from our group demonstrated PFC-dependent behavioral impairments and aberrant spike-timing dependent synaptic plasticity in PFC pyramidal neurons following chronic intermittent ethanol (CIE) vapor inhalation. Thus, it is possible that chronic alcohol exposure may induce neuroadaptations in the mPFC that are associated with maladaptive decision-making that is a hallmark of alcohol use disorders. These experiments address CIE exposure-induced structural and biochemical plasticity of glutamatergic synapses in the prelimbic (PL) mPFC. We determined the effect of CIE exposure on dendritic spine morphology and subunit composition

of glutamate receptors in the PL mPFC immediately following CIE exposure and 1 week post-withdrawal. Dendritic spine analysis indicates that CIE exposure produces a significant and persistent increase in mature mushroom spines without altering overall dendritic spine density or spine length. The morphological neuroadaptations were associated with an increase in both GluN1 and GluN2B subunits of the NMDA receptor in a PSD-enriched fraction immediately after CIE exposure. However, these changes were no longer present when examined 1 week post-exposure. CIE exposure did not alter the expression levels of the GluR1 subunit of AMPA receptors at either time point. Taken together, the findings from these studies suggest that CIE exposure induces changes in dendritic spine morphology and glutamatergic subunit composition in the PL mPFC, suggesting that these neuroadaptations may contribute to the cognitive dysfunctions that characterize addictive processes.

Title: Danger signals HMGB1, TLRs, and RAGE are increased following adolescent intermittent ethanol treatment in adult rats and in human alcoholic post-mortem prefrontal cortex

Authors: *R. P. VETRENO[1], L. QIN[2], F. T. CREWS[2]
[1]Sch. of Med., The Univ. of North Carolina - Chapel Hill, Chapel Hill, ; [2]Sch. of Med., The Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Adolescence is a critical period of prefrontal refinement, neuroplasticity, and increased risk-taking and sensation seeking that promotes the acquisition of skills necessary for adult independence. This period is also a time of considerable alcohol experimentation and abuse that prompted the hypothesis that adolescent binge drinking might exert long-term effects on adult brain and behavior. Our laboratory recently linked alcohol-induced neuroinflammation to neurodegeneration through the induction of innate immune danger signaling (i.e., high-mobility group box 1 [HMGB1]-Toll-like receptor [TLR]-receptor for advanced glycation end-products [RAGE] signaling). To determine whether adolescent binge drinking increased innate immune danger signaling in the adult brain, male Wistar rats received adolescent intermittent ethanol

(AIE [5.0 g/kg, i.g., 2-day on/2-day off schedule]) treatment from P25 to P55. During abstinence, reversal learning was measured, and 25 days later (P80) tissue was collected for danger signal expression assessment. Adult rats exposed to AIE had increased levels of TLR4 mRNA (>400% increase) and TLR3 mRNA (>300% increase) relative to controls as well as increased TLR4, TLR3, and RAGE immunohistochemical (IHC) protein expression, which was approximately double control levels in the adult prefrontal cortex. This persistently upregulated receptor expression was accompanied by increased expression of the danger signal receptor agonist, high-mobility group box 1(mRNA: 160% increase; IHC protein: 150% increase). Behavioral assessments indicated that AIE exposure did not alter Barnes maze spatial learning, but did induce long-term reversal learning deficits while increasing perseveration. Danger signal receptor expression correlated with reversal learning deficits. Human post-mortem brain assessment found increased danger signal expression in alcoholic orbitofrontal cortex, which correlated with lifetime alcohol consumption and age of drinking onset. Together, these findings provide evidence that adolescent binge drinking leads to long-term activation of innate immune danger signaling that contributes to adult neurocognitive dysfunction.

Title: Embryonic and post-embryonic effects of the designer drug mephedrone on early neurogenesis and learning

Authors: A. ADAM[1], C. ZSEDENYI[1], *A. L. CSILLAG[2]
[1]Dept. of Anatomy, Histology and Embryology, [2]Semmelweis Univ. Med., Budapest, Hungary

Abstract: The designer stimulant
4-methylmethcathinone (mephedrone) is a new and popular drug of abuse widely
available on the Internet and still legal in some parts of the world. Given the
fact that pregnant females may also be exposed, gestational damage
to the brain of the developing embryo is likely to occur. Earlier work on
neuroactive drugs has indicated impairment of neurogenesis following developmental exposure
of embryonic brain regions such as the hippocampus or in cell cultures relevant to adult

neurogenesis. Here we present
data on the effect of a cathinone derivative mephedrone, administered in ovo, on the development of specific regions of chicken striatum as well as on early adaptive learning of young post-hatch chicks. In the first group of experiments, mephedrone (2 mg/kg egg weight) was injected into incubated chicken eggs in critical stages
(days 6-10) of striatal development. This was followed by quantitative analysis of post-embryonic proliferating neurons in the subventricular zone of striatum, based on incorporation of the labeled nucleoside BrdU, visualized
by immunohistochemistry, and quantified by stereological method. A decrease in the density of BrdU-labeled cells
in the subventricular zone of subpallium including the medial striatum, nucleus accumbens and striopallidal organ was observed primarily in those birds injected in ovo in the later phase of striatal neurogenesis (day 10 of incubation). To investigate the effect of direct
post-hatch drug exposure on learning ability, one-day old chicks injected i.p. with mephedrone (10 mg/kg b.w.) were tested for the passive avoidance learning task. No impairment of memory retention was evident when the drug was administered 30 min prior to training. The drug-injected birds showed hyperactivity without apparent distress at the time of recall testing (6 h).

Abstract: Psychoactive drug consumption during pregnancy interferes with fetal brain development, with psychiatric, neurologic and cognitive deleterious long-term consequences. The effects of caffeine, the most widely consumed psychoactive substance, on brain development, are largely unknown. Since caffeine is a naturally-occurring antagonist of adenosine receptors, which regulate numerous intracellular processes, we investigated the consequences of exposing dams to caffeine, throughout gestation until weaning, on their offspring. Here we report that caffeine, or a type 2A adenosine (A2A) receptor antagonist, delayed the migration of GABAergic neurons and their insertion into the hippocampal circuitry, and increased network excitability during the first postnatal week. Early life caffeine exposure had long-term consequences in adult offspring, with a loss of hippocampal GABA neurons and robust cognitive deficits. These results demonstrate the deleterious effects of maternal caffeine consumption during development, through its action on A2A receptors, compromising the structural and functional properties of neuronal networks in offspring.

Title: Changes in frontal cortical BDNF and Glutamate receptor expression produced by prenatal cocaine exposure are heritable via epigenetic mechanisms

Authors: *D. M. MC CARTHY[1], J. ZHU[1], S. B. DARNELL[2], G. R. SANGREY[2], P. G. BHIDE[1], G. SADRI-VAKILI[2]

Abstract: Prenatal cocaine exposure impairs fetal brain development and produces long-term alterations in cognitive function. Animal models of prenatal cocaine exposure confirm changes in multiple events associated with brain development, including neurogenesis and neuronal migration. There is also evidence that alterations in gene expression influence behavior that can be inherited across multiple generations via epigenetic modifications. The effects of exposure to environmental factors such as cocaine appear to become incorporated into the germ line through the sustained expression of associated epigenetic marks. We used a mouse model to test the hypothesis that prenatal cocaine exposure produces epigenetic alterations that are manifested as biochemical and behavioral changes and transmitted across multiple generations. We exposed timed-pregnant Swiss Webster mice to cocaine from the 8th day of pregnancy until parturition. The offspring (F1 generation) upon reaching maturity showed decreased cocaine sensitization and increased expression of BDNF and glutamate receptor mRNA in the frontal cortex. The increased BDNF mRNA expression was associated with increased histone H3 acetylation. We crossed the F1 females (prenatally exposed to cocaine) with drug naïve males to produce the F2 generation. Similarly, the F2 females were crossed with drug naïve males to produce the F3 generation. Remarkably, the F2 and F3 progeny also showed the frontal cortical gene expression changes observed in the F1 generation, even though neither the F2 nor the F3 mice were directly exposed to cocaine. Our results indicate that changes in frontal cortical gene expression produced by the prenatal cocaine exposure may be heritable via epigenetic mechanisms

Title: Effects of prenatal methamphetamine exposure on adult cognitive performance

Authors: *J. H. HARKNESS[1,2], E. EASTWOOD[1,2], J. M. LOFTIS[6,2,3], J. RABER[1,2,4,5], T. J. PHILLIPS[1,2,6]

Abstract: Prenatal exposure to methamphetamine (MA) has been suggested to cause developmental and cognitive deficits in adulthood. However, due to polydrug abuse, pure MA effects are difficult to study in humans. Methods have not yet been described in the literature for a prenatal MA exposure model in mice that can be used to examine behavioral consequences associated purely with MA. The present experiments used a twice daily 8 mg/kg MA treatment regimen to explore effects of prenatal MA exposure on adult (~85 day old) spatial navigation learning using an 8-day Morris Water Maze task. In addition, brain tyrosine hydroxylase (TH) levels were measured in gestationally saline- and MA-treated neonatal mice. C57BL/6J x DBA/2J F1 mice were mated, and dams were administered MA for 19 days of gestation. Mice were first trained to swim to a visible platform in each quadrant of the water maze over 2 days, and then over 2 days to a "hidden" platform submerged immediately below the surface of the water in a target quadrant, where room cues could be used for navigation. Following the 4 days of training, a probe trial (no platform) tested spatial memory retention. Subsequently, over the next 2 days, mice were trained to find the hidden platform in a new location ("reversal" training), and were tested the following day in a reversal probe trial for recall of the new target location. There were no significant effects of gestational MA on distance traveled or swimming velocity in either probe trial or on body weight. Adult mice that had been exposed to MA during gestation tended to spend less time in the target quadrant than saline-treated mice in the first probe trial ($p=.07$), and spent significantly less time in the new target quadrant ($p=.03$) and the platform zone within the new target quadrant ($p=.008$) during the reversal probe test than saline-treated mice. Furthermore in the reversal probe trial, male MA-exposed mice spent a significantly greater percentage of time ($p=.0006$) in the original target quadrant, compared to saline-treated mice. These findings indicate that prenatal MA exposure may have long-term effects on spatial cognitive ability, and may significantly affect the plasticity of learning in these tasks. This regimen of MA exposure significantly decreased brain TH levels of postnatal day 1 pups to about 50% of levels in saline-treated controls ($p<.05$). Here we report prenatal MA exposure effects on brain TH levels, and lasting effects on spatial cognitive ability. This model of prenatal MA exposure should be useful for studying the effects of prenatal MA exposure without the confound of possible effects of other drugs, which is difficult to accomplish in humans.

Title: Developmental methamphetamine exposure decreases the number of vasopressin-immunoreactive cells in the hypothalamic paraventricular nucleus

Authors: *D. G. ZULOAGA[1], J. A. SIEGEL[2], J. RABER[1]
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]Sewanee: The Univ. of the South, Sewanee, TN

Abstract: The psychostimulant methamphetamine is abused by approximately 1.2 million individuals over the age of 12. Women that abuse methamphetamine might also do so while pregnant. Exposure to methamphetamine during brain development can lead to long-term behavioral and cognitive deficits. Methamphetamine can induce detrimental effects by increasing circulating levels of glucocorticoids. This can lead to long-term disruptions in the hypothalamic pituitary adrenal (HPA) axis, which plays a critical role in the regulation of stress responses. Furthermore, alterations in proteins and neuropeptides associated with the HPA axis, including vasopressin and glucocorticoid receptors, are correlated with disorders of anxiety, depression and cognition. We hypothesized that methamphetamine exposure during the stress hyporesponsive period would result in lasting alterations in the expression of HPA axis-associated proteins and/or neuropeptides and that these effects may contribute to alterations in stress responses reported in adult rodents treated with methamphetamine during brain development. To begin testing this hypothesis, male mice were treated with methamphetamine (5 mg/kg daily) or saline from postnatal day 11-20, a period of development in mice that models a similar period of brain development in humans that occurs in utero during the third trimester. In adulthood, mice were perfused for immunohistochemical detection of the glucocorticoid receptor and vasopressin within brain regions associated with the HPA axis. Our results indicate a decrease in the number of vasopressin-immunoreactive cells within the hypothalamic paraventricular nucleus (PVN) of mice treated with methamphetamine. As vasopressin also contributes to the regulation of cognition, decreased vasopressin may be one mechanism through which developmental methamphetamine exposure contributes long-term deficits in this function. No significant differences in glucocorticoid receptor expression were found in the hippocampus, PVN, or central amygdala. Thus, developmental exposure to methamphetamine can result in lasting

alterations in the vasopressin system, which may in turn affect stress-related behaviors, including those following chronic stress, and cognition.

Title: Cocaine intravenous self-administration (IVSA) in adult Long-Evans rats exposed to polychlorinated biphenyls throughout gestation and lactation

Authors: *M. M. MILLER, A. E. MEYER, J. L. NELMS, P. E. DICKSON, M. A. WARD, M. CALTON, H. J. K. SABLE
Dept Psychology & Biol. Sci., Univ. of Memphis, Memphis, TN

Abstract: Polychlorinated biphenyls (PCBs) are ubiquitous and persistent in the environment and pose a serious human health threat. Developmental exposure to PCBs in rats has been shown to produce alterations in brain dopamine (DA) concentrations that persist into adulthood. These alterations suggest that the reinforcing properties of drugs of abuse which act on the DA system may be affected by developmental PCB exposure. Our previous research has revealed that stimulation-evoked DA efflux in the nucleus accumbens (NAc) following stimulation of the medial forebrain bundle was significantly higher in rats developmentally exposed to PCBs following acute injections of cocaine, but attenuated (relative to non-exposed controls) following chronic cocaine injections. Thus, given that PCB exposure altered the dopaminergic response to cocaine, it was hypothesized that PCB exposure would influence cocaine self-administration (IVSA). In particular, the enhanced DA release seen in animals exposed to PCBs during gestation and lactation was expected to promote faster acquisition of cocaine self-administration during adulthood. Female Long-Evans rats were orally exposed to 0, 3 or 6 mg/kg/day of an environmentally relevant mixture of PCBs beginning 4 weeks prior to breeding and continuing until litters were weaned on postnatal day 21. One male and female per litter were food deprived around PND 90 to 85% of their free-feeding weight and trained to lever press (FR 5) for a food

reinforcer. Between PND 120-180, rats were surgically implanted with a jugular catheter and given a minimum of 48 hours for recovery. After the lever-press response to food was re-established, the reinforcer was changed to a 50µl infusion of 250µl of cocaine. The criterion for meeting acquisition was defined as <15% variability in reinforcers delivered over three consecutive days of testing. Preliminary data indicates that male rats developmentally exposed to 6 mg/kg/day PCBs reach criterion for cocaine IVSA in about half as many sessions as non-exposed controls. A similar but more variable trend occurs in the females. Together, these findings suggest that developmental exposure to PCBs can modify DA pharmacology in a manner that may promote cocaine drug-seeking behavior.

Title: Effect of chronic oral methylphenidate treatment and abstinence on dopamine transporter (DAT), D1R, and D2R binding in young rats

Authors: *L. S. ROBISON[1,2,3], M. ANANTH[1], J. M. SWANSON[4], J. K. ROBINSON[3], G.-J. WANG[1], N. D. VOLKOW[2], P. K. THANOS[1,2,3]

Abstract: Methylphenidate (MP) is widely used in the treatment of children and adolescents with ADHD. Since MP's mechanism of action is partly mediated by its ability to block DA transporters (DAT) and increase levels of extracellular dopamine in the striatum and nucleus accumbens (Volkow, et al. 2001); (Volkow et al. 2002a); (Volkow et al. 2002b), this has raised concerns regarding neuroadaptations in dopamine signaling that could increase their risk for substance use disorders in adulthood. Here, we investigate the effect of chronic MP treatment initiated in adolescence on dopamine receptor levels (D1 and D2) and DAT in adulthood.

Male Sprague-Dawley rats were split into 3 groups (*n=16/group)* at 4 weeks old: control (water), low dose MP (LD), and high dose MP (HD). A two-bottle 8-hour limited access drinking paradigm was utilized, producing an MP pharmacokinetic profile similar to human patients (Steier et al., 2008). Rats drank from the first bottle [4 mg/kg MP (LD) or 30 mg/kg MP (HD)] for the first hour. This bottle was replaced with a second bottle [10 mg/kg (LD) or 60 mg/kg MP (HD)], which was available for hours 2-8. Control rats were given water in both bottles. After 13 weeks of treatment, half of the rats in each group were sacrificed (n=8/group), and the remaining rats (n=8/group) underwent 5 weeks of abstinence (given water for the 8h drinking period) and were then sacrificed. Brains were harvested, flash-frozen, sectioned at 14µm, and stored at -80 °C. *In vitro* autoradiography was performed to assess MP's effects on levels of DAT and dopamine receptors D1R and D2R, using [^{3}H] WIN35,428, [^{3}H] SCH23390, and [^{3}H] spiperone, respectively.

MP treatment resulted in increased D1R density in the olfactory tubercle (LD: 5.1%, $p<0.05$; HD: 10.4%, $p<0.001$) and caudal portion of the dorsal CPu (HD: 37.1%, $p<0.001$), and decreased D1R binding in the ventrolateral CPu (rostral portion; LD: 5.0%, $p<0.05$). These effects were not observed in rats that had undergone subsequent abstinence from MP. MP was previously found to result in decreased D1R density in the CPu and olfactory tubercle (Carey et al., 1998); however, while treatment began at 4 weeks of age, dose, route of administration (3 mg/kg i.p.), and treatment length (2 weeks) differed from our study. Neither dose of MP changed D2R density, similar to prior findings (Carey et al., 1998; Randall et al., 1999) but distinct from prior results in which we showed that HD MP treatment (8 weeks) decreased D2R availability in the CPu, using microPET with [^{11}C] raclopride (Hwang et al., 2008). This discrepancy could result from increased dopamine release after chronic MP, rather than a reduction in D2R levels. Analysis of the DAT binding data is ongoing.

Title: 3-dimensional diffusion tensor imaging (dti) atlas of the rat brain in postnatal day 5, 14, and adulthood.

Authors: *A. RUMPLE[1], P. MAKAM[1], M. RADCLIFFE[1], J. LAUDER[1], M. MCMURRAY[2], I. OGUZ[1], J. JOHNS[1]
[1]UNC Chapel Hill, Chapel Hill, NC; [2]UIC, Chicago, IL

Abstract: Anatomical atlases play an important role in the analysis of neuroimaging data in rodent neuroimaging studies. Having a high resolution, detailed atlas can, not only expand understanding of rodent brain anatomy, but also enables automatic segmentation of new images, thus greatly increasing the efficiency of future analysis when applied to new data. This project seeks to develop and produce a set of detailed 3D anatomical atlases of the rat brain at postnatal day five (P5), fourteen (P14), and adult dams to be used for analysis of anatomy in a study focused on intrauterine cocaine abuse in relation to neurodevelopment as well as for use with future data sets.

Our methods consisted of first creating a template image based on fixed scans of control rats, then manually segmenting various individual brain regions on the template. The subjects were Sprague-Dawley rats that served as controls from a study focused on intrauterine cocaine exposure and development. They were euthanized and underwent fixation before being scanned overnight for approximately fifteen hours. For each atlas, the template image was an average of fixed scans of control rats for that age. The P5 and P14 templates were made from scans of twenty rats each (ten female and ten male). The adult dam template was made from the scans of six female rats. All DTI scans were acquired on a 9.4T Bruker scanner. The resolution for the adult dam scans was (0.16 x 0.125 x 0.16)mm^3 with twelve gradient directions and two baseline images; the resolution of the P5 and P14 images was (0.12 x 0.07 x 0.12)mm^3 with twenty-one gradient directions and three baseline images. The individual cases were first resampled to isotropic resolution, then manually skull-stripped, then deformably registered via an unbiased atlas building method to create a single template image. This template was used to segment the individual brain structures.

Using itkSNAP software, subcortical regions, including both white matter and gray matter structures, were manually segmented in the axial, sagittal, and coronal planes. The adult dam, P14, and P5 atlases had twenty-nine, forty-five, and thirty-nine regions segmented out, respectively.

We created a high-resolution anatomical atlas of pup and adult rat brains. This atlas can now be used to analyze images from live scans of individual cases; it can be easily used on lower resolution images so that the segmentation of future images can be completed more efficiently and robustly. Currently, we are working on applying these atlases to the live images generated from this study and are acquiring results of cocaine's effects on development. These atlases will be made available to the broader research community.

Title: Preadolescent behavioral responsivity to an acute injection of cocaine

Authors: A. URUENA[1], *C. L. KIRSTEIN[2]
[1]USF, Tampa, FL; [2]Univ. South Florida Tampa, Tampa, FL

Abstract: It has become increasingly well known that exposure to drugs of abuse during early developmental time periods impacts neurodevelopmental processes. Such drug-induced alterations may contribute to the observed vulnerability in developing drug addiction later in life. Past investigations have demonstrated age- and dose-dependent differences in acute cocaine-induced behavioral responsivity. Recent reports have shown a dose-dependent augmentation in locomotor activity in response to acute cocaine administration in naïve adolescent rats, as compared to naïve adult rats. Such findings demonstrate drug sensitivity is greater during adolescence than during adulthood, suggesting the rewarding properties of cocaine may be greater during different developmental time periods. In order further assess ontogenetic differences in drug sensitivity, established experimental procedures were employed to investigate the behavioral profile of preadolescent rats exposed to an acute injection of cocaine. Naïve male preadolescent rats (postnatal (PND) 25) were habituated to a novel open-field arena for 20 minutes. Following habituation, rats were administered either cocaine (20 mg/kg, i.p.) or a saline vehicle. The 20 mg/kg dose of cocaine was used as this dose has been shown to effectively increase locomotor activity in all several age groups. Preliminary results show cocaine-induced hyperlocomotion as a result of a decrease in the frequency of immobile episodes (start/stops). When results were compared to rats previously tested at age PND 35, 45 and 60 (i.e. early and late adolescence, or adulthood, respectively), preadolescent rats demonstrated greater behavioral responsivity to acute cocaine administration compared to additional age groups. Further experimentation is warranted as such observations suggest a unique susceptibility to drug addiction as a function of increased drug sensitivity and drug reward during preadolescence.

Title: Cocaine and sucrose self-administration and cue-induced reward seeking in adolescent versus adult rats.

Authors: *D. S. COUNOTTE[1], K. KONKA[1], Y. SHAHAM[2], P. O'DONNELL[1]
[1]Anat. & Neurobio., Univ. of Maryland Baltimore, Baltimore, MD; [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Adolescence is a critical window of continued brain development, and a period during which individuals first come into contact with drugs of abuse. Epidemiological research suggests that early use of drugs is associated with more severe drug addiction in adulthood. Here, we investigated in rats whether adolescent cocaine self-administration followed by forced abstinence leads to enhanced drug seeking compared to rats that self-administered cocaine during adulthood. In a separate group of rats, we did a similar experiment with oral sucrose instead of cocaine.
For cocaine self-administration, adolescent rats were implanted with jugular vein catheters at P35 and adult rats were implanted at P65. They were allowed to recover for one week and started cocaine self-administration at P42 and P72, respectively. Active lever presses led to cocaine infusions (0.4 mg/kg/infusion) that were paired with a compound tone-light cue. After 10 days of cocaine self-administration, the rats were left in their home cage for four weeks until cue-induced cocaine seeking was assessed in a single extinction session in which an active lever-press led to presentation of the tone-light cue but not cocaine.
For sucrose self-administration we used a similar procedure, except that lever-presses lead to the delivery of 0.6 ml of 10% sucrose solution. Preliminary data indicate that young adolescent rats (starting at P35) self-administered less sucrose than adult and older adolescent (starting at P42) rats, even when the amount of sucrose was adjusted to body weight. Data on age differences in cocaine self-administration and cue-induced cocaine and sucrose seeking after a prolonged abstinence period will be presented at the meeting.

Title: Sex differences in induction and expression of methylphenidate sensitization and brain-derived neurotrophic factor (BDNF) in adolescent rats.

Authors: *R. ROEDING[1], M. K. PERNA[2], S. B. GRIFFIN[3], R. BECKER[3], R. W. BROWN[3]
[1]Psychology, [2]Quillen Col. of Med., [3]East Tennessee State Univ., Johnson City, TN

Abstract: Methylphenidate (MPH) is a psychostimulant that is used for the treatment of attention-deficit hyperactivity disorder that is often recreationally abused. Past studies have primarily analyzed the effects of MPH on behavior and BDNF using males as subjects, with studies showing a lack of behavioral sensitization, although the effect of MPH on BDNF has yielded contradictory results. BDNF is a neurotrophin ubiquitously found throughout the brain that plays an important role in synaptic maintenance and development and has been implicated in addiction. This study analyzed sex differences in induction and expression of MPH locomotor sensitization in adolescent male and female rats as well as the effects of MPH on BDNF protein in two brain areas of drug reward: the nucleus accumbens (NAcc) and striatum (STR), after both induction and expression of sensitization. After habituation to a locomotor arena, animals (N=6-8 per group) were administered MPH (5 mg/kg) or saline every other day from postnatal day (P)33 to 49 and tested for 30 min in the same arena with activity counts recorded. In one group, brain tissue was removed one day following testing and the NAcc and STR assayed for BDNF at P50. A different group of animals was raised to P60 and given an MPH (or saline) challenge. One day following the challenge, brain tissue was removed and the NAcc and STR were assayed for BDNF at P61. Females administered MPH demonstrated behavioral sensitization from P33 to P41, and then decreased in activity from P41 to P49. Females demonstrated a robust increase in locomotor activation as compared to males, which failed to demonstrate sensitization to MPH. However, both groups given MPH demonstrated an increase in activity compared to controls throughout sensitization testing. On the challenge at P60, females administered MPH demonstrated higher levels of activity compared to all other groups and were equivalent to their final day of sensitization. Males administered MPH also expressed sensitization, as they demonstrated increased behavioral activation as compared to saline-treated controls. Neurochemical analyses at P50 revealed that MPH produced a significant increase in striatal BDNF in males, but a significant decrease in striatal BDNF in females. There were no changes in

the NAcc. At P61, BDNF was increased in both STR and NAcc in males, and female data will be presented. These data demonstrate robust sex differences in behavioral activation and sensitization to MPH that is both induced and expressed in females, but only expressed in males. Further, MPH produces sex-dependent effects on BDNF, indicating sex differences in the brain plasticity response to MPH in adolescence.

Title: Methylphenidate conditioned place preference in adolescent male and female rats

Authors: E. D. CUMMINS, S. B. GRIFFIN, R. L. ROEDING, J. H. THOMAS, *R. W. BROWN
East TN State Univ., JOHNSON CITY, TN

Abstract: Methylphenidate (MPH) is a psychostimulant drug that is commonly prescribed for Attention Deficit-Hyperactivity Disorder (ADHD), however, this drug is also abused. The primary pharmacological action of MPH is similar to that of cocaine, in that the drug blocks the dopamine transporter and enhances dopamine neurotransmission. The similarity to cocaine has brought to light legitimate concerns at the abuse liability of MPH. The focus of the present study was to analyze MPH conditioned place preference (CPP) in adolescent rats, with the focus on sex differences in this effect. CPP is a commonly used measure of drug reward in rats. Animals were also tested at two different time periods, from postnatal day (P)32-38 or P43-49, representing periods during adolescence both before and after the commencement of the estrous cycle in females, which begins on approximately P41. After an initial preference test on P32 or 43 revealed no significant preference for either context, an unbiased procedure was used. Beginning on P33 or P44, MPH (5 mg/kg) was paired with either context in animals in the drug condition, balanced across males and females. Controls were given saline in both contexts (N=8-9 in all groups). A preference test was given on P38 or P49 with dividers removed. Results revealed no sex or age difference, but MPH induced a robust increased preference for the paired context in both males and females on the post-conditioning preference test, which was significantly greater

than male and female controls. Interestingly, males demonstrated significantly higher levels of activity and a higher number of entries made into the paired context when tested at the younger age, but there were no sex differences in these responses in older animals. Brain tissue is currently being analyzed for levels of the dopamine transporter (DAT), and this data will be presented. Past studies have shown that females have a higher number of DAT in the striatum compared to males in adulthood, but this has never been established in adolescence. In conclusion, it appears that a 5 mg/kg dose of MPH is capable of inducing drug reward in adolescent rats, and unlike recent results from our laboratory regarding behavioral sensitization, there are no sex differences in this response.

Physiological Sci. Dept., Santa Casa Med. Sch., Sao Paulo, Brazil

Abstract: The continuous and chronic treatment with cocaine (COCA) provokes anorexigenic effects, such as a diminished food-search behavior in animals and an appetite reduction in humans. Nevertheless, the majority of animal treatment protocols with COCA disregard the study of the abstinence periods, which are usually found in recreational use by humans. This work objective was to evaluate the food intake and body mass progression of animals submitted to a COCA chronic treatment that simulates the recreational use of this drug by humans. Forty male Wistar rats of ≈ 200 g were divided into 4 groups and submitted to 2 different protocols: a variable-dose administration protocol of COCA (VAR) and a continuous and fixed-dose administration protocol of COCA (CONT). Regarding VAR, 10 animals received variable doses of COCA (2 to 15 mg/kg, ip), and other 10 received saline (SAL), during 45 days, with alternating periods of abstinence and treatments, which could have from 2 to 7 days of COCA administration. The treatment period and established doses were determined by random numbers generated by an EXCEL spreadsheet. Regarding CONT, 10 animals received daily the average

dose used in VAR (4 mg/kg, ip) of COCA, during 45 days; and other 10 animals SAL. During the VAR treatment, the body mass was measured at the beginning and at the end of the abstinence or treatment periods. The body mass of the CONT group was measured weekly. The food intake was followed daily with the measurement of the initial ration mass minus the final ration mass. Regarding the VAR treatment, the COCA animals had an increased final food intake (COCA: 511.67 ± 25.39 g; SAL: 466.72 ± 15.28; $p \leq 0.0001$) and an enhanced body mass gain (COCA: Δ Body Mass 305 ± 36.06 g; SAL: 277.4 ± 24.86; $p \leq 0.010$), when compared to SAL. Nevertheless, the COCA animals submitted to CONT expressed a decreased final food intake (COCA: 453.67 ± 17.93 g; SAL: 491.5 ± 22.37; $p \leq 0.0001$), when compared to SAL. There were no significant differences regarding the body mass gain. The increased food intake and the enhanced body mass gain, regarding the COCA treated animals of both protocols, unveiled the lack of the anorexigenic effect classically observed in cocaine chronic treatments. The occurrence of intermittent abstinence periods and variable-dose administrations may be responsible for the plastic changes in the catecholaminergic systems related to the food intake control. Since the variable-dose treatment protocol with cocaine was developed to simulate the recreational use standards of the drug by humans, these results indicate that the VAR protocol may be useful to the understanding of the neuroplastic phenomena found in the abstinence of psychostimulant drugs.

Title: Methylphenidate exposure prior to adolescence (postnatal days 11-20) enhances cocaine reward in early, but not late adolescent rats

Authors: C. B. SHIN, R. FLORES, D. SAVEAU, D. F. COLLIN, J. GIANG, *A. R. ZAVALA
California State Univ., LONG BEACH, CA

Abstract: Methylphenidate is the most prescribed treatment for attention deficit hyperactivity disorder. Surprisingly, little research has been done examining the long-term effects of this drug, particularly when it is prescribed to preschool age children. In rats, exposure to methylphenidate early in development has been shown to produce long-lasting effects on the sensitivity to cocaine when animals are tested as adults. However, the effects of methylphenidate exposure on the sensitivity to cocaine in adolescent rats have not been previously investigated. Using the conditioned place preference (CPP) paradigm, we examined the effects of early methylphenidate exposure on cocaine reward in early and late adolescent rats. Male and female Sprague-Dawley rats were treated twice daily with methylphenidate (0, 2, or 4 mg/kg) from postnatal days (PDs) 11-20. Rats were then assessed for cocaine-induced CPP (2.5 mg/kg) beginning on PD 27 (early adolescence) or PD 41 (late adolescence). A 6-day CPP procedure was used, which included 1 preconditioning day, 4 conditioning days, and 1 test day. Results showed that in males, early methylphenidate (2 mg/kg) enhanced cocaine-induced CPP when animals were tested during early adolescence (PD 34). In contrast, methylphenidate pretreatment did not affect cocaine-induced CPP when male rats were tested during late adolescence (PD 48). In females, early exposure to methylphenidate at either dose increased cocaine-induced CPP during early (PD 34), but not during late adolescence (PD 48). The present data adds to a growing body of evidence that early methylphenidate enhances the rewarding value of cocaine, particularly during early periods of development.

Title: Sex and developmental differences in dopamine transporter and autoreceptor regulation of phasic dopamine in nucleus accumbens of rats.

Authors: *Q. D. WALKER, C. M. KUHN
Pharmacol. & Cancer Biol., Duke Univ. Med. Ctr., DURHAM, NC

Abstract: Illicit drug use and the development of addiction exhibit important sex- and age-specific differences. The rat may be a useful animal model to study biologic sex and age

differences in the dopamine system that might mediate these observed human patterns. We have shown that cocaine induces less behavioral stimulation and electrically-stimulated dopamine efflux in dorsal striatum in the adult male rat relative to adult females and adolescent male and female rats. The present studies investigated sex and age differences in spontaneous dopamine transients and tonic dopamine levels in nucleus accumbens shell using cyclic voltammetry in prepubertal (PN28) and adult (PN70+) urethane-anesthetized rats. Basal transient frequency and duration were greater in adult than adolescent accumbens shell, while amplitude trended higher in females than males. Injection of 15 mg/kg cocaine i.p. increased transient frequency and amplitude more in adolescent than adult animals and adult males were less affected than females. The D2 antagonist, 2 mg/kg raclopride s.c., increased dopamine transients most in adult males and least in adult females. Cocaine enhanced phasic dopamine more rapidly in adolescents than adults. Simultaneous change in tonic dopamine over 15 or 30 min following systemic drug administration was determined by principal components regression. Cocaine increased extracellular dopamine more in both groups of adolescents than adults (1 µM vs 0.5 µM) and acute raclopride induced the biggest increase in adult males. Interestingly, raclopride pretreatment tripled the tonic dopamine increase by cocaine in all groups except adult males, where little enhancement was observed. Tonic increases induced by cocaine were also more rapid in adolescents. The greater cocaine-stimulated motor effects in female than male adult rats were better reflected in the present robust sex differences in cocaine effects on phasic dopamine. D2 autoreceptor regulation of dopamine transients increased during development in males but decreased in females, indicating sex-specific development of autoreceptor regulation. The present results showed that spontaneous dopamine release events mirrored, and suggest that they may mediate (at least partly), the observed sex and age differences in the behavioral effects of cocaine in rats.

Title: Transgenerational epigenetic modifications in response to adolescent morphine exposure in female rats.

Authors: *E. M. BYRNES[1], N. L. JOHNSON[1], J.-E. OH[2], J. GAL-TOTH[4], N. CHAMBWE[3], F. CAMPAGNE[3], M. TOTH[2]
[1]Tufts Univ. Cummings Sch. Vet Med., North Grafton, MA; [2]Pharmacol., [3]Inst. for Computat. Biomedicine, Weill Cornell Med. Col., New York, NY; [4]The Rockefeller Univ., New York, NY

Abstract: Adolescent opiate use has increased over the past decade with unknown consequences on development during this critical period. For several years we have used the rat to identify transgenerational consequences of female adolescent opiate exposure with morphine serving as the prototypical opiate. These studies have revealed significant neural, endocrine and behavioral effects in the F1 generation of adolescent morphine exposed females (F0 MOR) when compared to the offspring of adolescent saline-exposed females (F0 SAL). It is important to note that all females are drug-free for several weeks prior to mating and thus direct effects of morphine on the developing fetus are not possible. Recent behavioral data observed alterations in anxiety-like behavior and significant disruption of object recognition in F1 MOR females. Moreover, these effects continued to be observed in F2 MOR females as well as in F1 MOR females that were reared by an untreated donor mother. These behavioral findings suggest that adolescent morphine exposure leads to epigenetic modifications that are maintained beyond the F1 generation. To begin to elucidate the mechanisms underlying these transgenerational effects, methylation patterns were determine in the dorsal CA1 region of the hippocampus, a region that regulates both anxiety-like behavior and recognition memory. Differential methylation at CpG sites in dorsal CA1 neurons was determined by "reduced representation bisulfate sequencing (RRBS)" comparing adult MOR and SAL female offspring from both the F1 and F2 generation. We profiled approximately 2 million CpG sites at 35x coverage (approx. 10% of all CpG sites in the mouse genome). We found significant methylation changes (BH corrected p<0.05 and delta methylation rate >20%) at approx. 100K sites in F1 MOR and at approx. 30K sites in F2 MOR samples. This indicates a substantial genome-wide effect of adolescent morphine in the F1 offspring that can reach the F2 generation. Importantly, there was a significant overlap between the F1 and F2 changes (at approx. 6K sites) suggesting that a fraction of the F1 methylation changes are reproduced across generations. Co-segregation of these methylation changes with the behavioral changes may indicate their role in the transgenerational effect of adolescent MOR.

Title: Response inhibition and Brodmann Area 45 volume in adolescents with prenatal drug exposure.

Authors: *K. A. CACIC[1,2], B. J. SALMERON[1], T. RIGGINS[2], S. BUCKINGHAM-HOWES[3], L. SCALETTI[3], T. J. ROSS[1], M. M. BLACK[3]
[1]NeuroImaging Res. Br., Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Univ. of Maryland, College Park, MD; [3]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The objective of the present study was to examine the influence of prenatal drug exposure on cortical frontal volumes involved in cognitive performance in a well-characterized sample of 51 adolescents (27 with a history of PDE and 24 from a comparison group of community controls (CC); mean age = 14 years). Inclusion criteria for the PDE group included a positive maternal or infant toxicology screen at time of birth for cocaine and/or heroin or reported use of either substance during the last 6 months of pregnancy. PDE participants were recruited at birth while CC participants were born at the same hospital and recruited from the same primary care clinic in which all participants were followed. The groups were well-matched on socioeconomic measures. Data was collected on a 3-T Siemens Allegra scanner with whole-brain oblique axial T1-weighted images (1-mm3 isotropic voxels: TR=2.5 s, TE=4.38 ms, FA = 80°). Cortical reconstruction and volumetric segmentation were completed in Freesurfer. Initial analysis with total cortical gray matter as the only covariate revealed that bilateral BA 45 differed between groups such that PDE adolescents had smaller volumes than CC adolescents. The BA 45 has previously shown involvement in response inhibition and cognitive control tasks. Therefore, differences in Continuous Performance Task (CPT) performance were examined in conjunction with the volumetric difference. Results revealed adolescents with a history of PDE had a “riskier” response style than controls on a CPT response inhibition task (tended towards more errors of commission than omission). Further analyses considered: age at time of scan, gender, IQ, prenatal exposure to alcohol and tobacco, indices of early childhood environment (i.e. caregiver depression, primary caregiver, caregiver changes through age 7) and primary caregiver at the time of assessment. After multiple covariates adjustment, significant differences remained between right BA 45 volumes and CPT response style. Furthermore, right BA 45 volume was positively correlated with CPT response style such that larger volumes were associated with higher response style scores, indicating progressively “safer” response styles.

These findings provide support for long-terms effects of PDE on response inhibition and point to neural mechanisms that may underlie these outcomes.

Title: Dextromethorphan attenuate inflammatory and dependence in opioid dependent patients

Authors: *S. CHEN[1], S. LEE[2], M. WEN[2], R. LU[2]
[1]Departmen of Psychiatry, Natl. Cheng Kung Univ., Tainan, Taiwan; [2]Psychiatry, Col. of Med. & Hospital, Natl. Cheng-Kung Univ., Tainan, Taiwan

Abstract: Abstract Recent studies show that overactive glia cells and their secretions, especially proinflammatory cytokines, might be related to the development of opioid dependence. We evaluated whether the inflammatory process is related to the progression of opioid dependence. A double-blind, randomly stratified clinical trial to investigate whether add-on dextromethorphan (DM, 60-120 mg/day), attenuated inflammation and dependence in opioid abused patients with methadone maintenance therapy (MMT). All participants (107 opioid dependent patients and 113 nondependent healthy controls) were recruited from National Cheng Kung University Hospital. Their plasma cytokine levels and opioid concentration were measured to evaluate the effect of add-on DM. Plasma TNF-α and IL-8 levels were significantly higher in long-term opioid dependent patients than in healthy controls ($p < 0.001$). We also found that the plasma cytokines levels were significantly positive correlated to the heroin abused years, which indicates the possibility of an inflammatory process after long-term opioid use. These patients were then accepted for the MMT combined with placebo or DM treatment. After 12 weeks of treatment, plasma cytokine TNF-α and IL-8 levels were significantly attenuated in both the DM 60 mg and the DM 120 mg group ($p < 0.05$), but not in the placebo group. In addition, the methadone oral dose in the placebo group gradually increased from 100% to 117 ± 9.9% at 12 weeks, which suggests that MMT patients become tolerant to methadone when it is used alone. The methadone doses in the DM 60 mg and DM 120 mg groups, however, decreased from 100% to 91.6±5.2% and 93.2±5.3%, respectively, at 12 weeks. Moreover, analyses of urinary and plasma morphine

levels showed that the combined used of opioid was worsened in the placebo group, but that it did attenuate in the two add-on DM groups. These results suggested that dextromethorphan may be used to attenuate inflammatory process, inhibit tolerance of methadone and opioid abuse in opioid dependent patients.

Title: AMPA receptors in central amygdala mediate pain-induced suppression of opioid reward

Authors: *Y.-Y. HOU, Z. ZHANG, Y.-Q. CAI, Y. XIA, W. WANG, Z. PAN
Pain Med., MD Aderson Cancer Ctr., Houston, TX

Abstract: Pain and reward have opposite emotional, motivational effects and functionally influence each other. Opioids are powerful pain-relieving drugs that also have strong rewarding effects for opioid addiction, which limit their optimal prescription use for control of chronic pain. The neurobiological mechanisms underlying functional interactions between chronic pain and opioid reward are unclear. We examined the role of GluR1 and GluR2 subunits of AMPA receptors in the central nucleus of the amygdala (CeA) in regulation of pain impact on the rewarding properties of opioids. We found that CFA-induced persistent pain time-dependently decreased morphine craving in rats self-administrating morphine. Pain relief by pretreatment with indomethacin, a non-steroidal anti-inflammatory drug, largely reversed CFA-induced suppression of morphine intake. Western blotting revealed that morphine self-administration, but not passive morphine injection, increased synaptic GluR1 level and decreased synaptic GluR2 level in the CeA, whereas total GluR1 and GluR2 protein levels were unchanged, indicating morphine self-administration-induced membrane trafficking of GluR2-lacking AMPA receptors. In contrast, CFA-induced pain elevated both synaptic GluR1 and GluR2 levels in saline control rats. However, in morphine self-administrating rats, CFA-induced pain significantly decreased both GluR1 and GluR2 levels in the CeA, which was reversed by indomethacin pretreatment. These data indicate that GluR2-lacking AMPA receptors in the CeA play an important role in

mediating opioid reward and the impact of persistent pain on opioid reward may depend on the emotional state and the time course of pain development through regulation of relative synaptic expression of CeA GluR1 subunits.

Title: NMDA receptors in the hippocampus underly morphine-induced alterations in synaptic plasticity.

Authors: *A. K. FAKIRA, G. S. PORTUGAL, B. CARUSILLO, Z. MEYLAN, J. MORON CONCEPCION
Anesthesiol., Columbia Univ. Med. Ctr., New York, NY

Abstract: Previous studies in our laboratory demonstrate that escalating doses of morphine paired with a novel context produced robust locomotor sensitization and impaired long term potentiation (LTP) in the hippocampus. Whereas behavioral sensitization was attenuated by mutating Ca2+ permeable AMPA receptors in the hippocampus LTP remained impaired. Ca2+ permeable NMDA receptors, composed of NR2A, NR2B and NR1 subunits, are negatively regulated by Ca2+-activated small-conductance potassium channels (SK channels) and modulation of this feedback loop can affect long-term potentiation (LTP). In this study we examined the role NMDA receptors (NMDAR) and SK2 channels in the mechanisms underlying morphine-induced alterations in synaptic plasticity. Mice displaying behavioral sensitization to escalating doses of morphine (5, 8, 10 and 15 mg/kg) after receiving a morphine challenge (5mg/kg; Mor + Mor) one week later demonstrated increased NR2A subunit trafficking to the hippocampal PSD and whole cell patch-clamp recordings from CA1 pyramidal cells showed that sensitivity of EPSCs to NR2A subunit blocker NVP is increased suggesting an increase in NR2A containing NMDA receptors. Moreover, sensitivity to NR2B blocker Ro 25-6981 is decreased in morphine treated animals suggesting morphine-induced changes in NMDAR composition. In addition to alterations in NMDARs, expression of SK2 channels is increased in the hippocampus of Mor + Mor mice. Furthermore, bath application of SK channel blocker apamin produced a

higher increase of NMDAR-EPSCs in Mor + Mor group compared to Sal + Mor, indicating enhanced activation of SK-channel-NMDAR feedback loop in morphine treated animals. Finally, we found that apamin application can restore the ability of CA1 cells to produce LTP.
Our data suggest that morphine-induced changes in NMDAR composition can affect SK channel-NMDAR loop leading to down-regulation of LTP. Therefore, we provide an evidence for a new key player to the mechanism of impaired synaptic plasticity after morphine-induced sensitization.

Title: Morphine effects on opioid, cannabinoid, and stress-related receptors in the locus coeruleus

Authors: *K. M. JAREMKO[1], B. A. S. REYES[1], A. S. MENKO[2], E. J. VAN BOCKSTAELE[1]
[1]Neurosci., Thomas Jefferson University, Farber Inst. for Neurosciences, Philadelphia, PA; [2]Pathology, Anat. & Cell Biol., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Opiate addiction contributes to the 193 billion dollars spent yearly in the United States on drug abuse, with approximately 2 million people currently addicted to heroin or non-medical prescription opiates. Chronic stress is known to negatively impact addiction recovery and the interaction between the stress axis and opioid circuitry has been demonstrated in the locus coeruleus (LC). The LC serves as the primary source of norepinephrine (NE) with diffuse projections throughout the brain and is reciprocally regulated by endogenous opioids and the stress-related neuropeptide, corticotropin releasing factor (CRF). Previous work has shown that chronic morphine sensitizes the LC to the stimulatory effects of CRF (Xu et al., J Neurosci, 24: 8193-8197, 2004). We previously showed that the mu-opioid receptor (MOR) co-localizes with LC dendrites that contain the CRF receptor (CRFr) (Xu et al., J Neurosci, 24: 8193-8197, 2004). Additionally we have shown that the cannabinoid-1 receptor (CB1r) is found within MOR labeled somatodendritic profiles, as well as within axon terminals contacting MOR dendrites in the LC (Scavone et al., Brain Research 1312**:** 18-31, 2010). The LC is uniquely poised to be a

site of convergent actions of opioid, cannabinoid, and stress pathways that modulate NE output. In the present study, we investigated protein expression levels for MOR, phosphorylated MOR, CB1r, and CRFr in the LC following acute exposure to morphine. Male Sprague Dawley rats were injected systemically with morphine or saline and euthanized following a period of 1 hour. Western blot analysis revealed no significant difference in expression levels for CRFr, MOR or phosphorylated MOR following acute exposure to morphine in LC extracts when compared to control. In a separate cohort, rats were implanted with morphine or placebo pellets for 7 days and withdrawal was elicited by subcutaneous injection of naltrexone, a MOR antagonist. Co-immunoprecipitation analysis of MOR and CB1r in LC extracts following withdrawal revealed an unexpected association between the two receptors in rats subjected to antagonist precipitated withdrawal when compared to control. Investigating the intersection between opioid, cannabinoid, and stress signaling systems in the LC after morphine exposure may uncover broader circuit-based interactions that impact noradrenergic signaling and potentially elucidate novel targets for the treatment of opiate addiction.

Abstract: Evidence has shown that genetic factors may interact with environmental modulators to promote heroin addiction and relapse after withdrawal. ZNF804A (zinc finger protein 804A) rs1344706 is a schizophrenia risk gene that was first identified by genome-wide association studies and associated with a large set of psychiatric disorders. Using structural magnetic resonance imaging and behavioral tasks, we investigated the effect of a ZNF804A rs1344706 polymorphism on gray matter volume and neurocognitive performance in heroin addicts and healthy controls. We found a significantly high frequency of the T allele in heroin addicts. Heroin addicts showed impaired decision-making on the Iowa Gambling Task, and the impairment was aggravated as the T allele dose increased. Brain imaging data were based on a subset of 76 heroin addicts and 78 healthy controls. The significant main effects of ZNF804A indicated that subjects who carried the T allele had larger gray matter volume in the temporal gyrus, parietal gyrus and frontal-insular cortex. Furthermore, a significant interaction between heroin addiction and genotype showed that gray matter volume in the dorsolateral prefrontal cortex exhibited a U-shaped curve as the T allele increased in addicts, but opposite changes were observed in controls. Overall, these findings might reflect differential genotypic effects of ZNF804A on brain morphology and neurocognitive performance in heroin addicts and healthy controls, suggesting a possible role of brain morphology as an endophenotype for future genetic studies on heroin addiction.

Title: Knockdown mu-opioid receptors in the ventral tegmental area: Critical effect on BDNF expression after intermittent social defeat stress

Authors: *C. E. JOHNSTON[1], A. W. LASEK[2], U. HEBERLEIN[3], R. P. HAMMER, Jr.[1,4], E. M. NIKULINA[4]
[1]Arizona State Univ., Tempe, AZ; [2]Dept. of Neurol., Univ. of California San Francisco, Emeryville, CA; [3]Dept. of Anat. and Program in Neurosci., Univ. of California San Francisco, San Francisco, CA; [4]Basic Med. Sci., Univ. of Arizona, Phoenix, AZ

Abstract: Intermittent social defeat stress produces an upregulation of mu opioid receptors (MOR) in the ventral tegmental area (VTA). This phenomenon also results in increased social avoidance and augmented locomotor responses, or sensitization, following amphetamine challenge. Research has shown that intermittent social defeat stress produces a prolonged induction of brain-derived neurotrophic factor (BDNF) in the VTA. Increased VTA BDNF expression has been tied to both enhanced susceptibility to stress-related behaviors and locomotor response to stimulants. Recently we have shown that MOR knockdown in the VTA is sufficient to prevent social defeat stress-induced amphetamine sensitization. In this study, we hypothesize that VTA MOR knockdown prevents social defeat stress-induced changes in the expression of BDNF. To test our hypothesis, lentivirus-mediated gene transfer and RNA interference were used to produce persistent depletion of MORs in the VTA of adult male Sprague Dawley rats. Bilateral infusions of either lentivirus-GFP-shRNA targeting MORs or a viral construct expressing a scrambled control sequence were made to the VTA. Starting one week later, social defeat stress and control handling procedures were administered four times in 10 days; social defeat stress was induced by a short confrontation with an aggressive male rat. Seven days after the last episode of social defeat stress, rats received an amphetamine challenge (1.0 mg/kg, i.p.) and their locomotor activity was measured. Brains were collected 10 days after amphetamine challenge. Immunohistochemistry was performed to quantify BDNF expression in the VTA. Tissue punches were taken for Western blot analyses in the nucleus accumbens (NAc) and prefrontal cortex. VTA MOR knockdown significantly reduced amphetamine cross-sensitization, which is consistent with our previous findings. BDNF expression increased significantly in the VTA after repeated social defeat stress in rats that received infusions of the scrambled control virus, however BDNF induction was prevented by intra-VTA MOR depletion. Western blots revealed a trend toward increased NAc BDNF expression in animals with intact MORs only after social defeat. There were no differences in BDNF levels in the prefrontal cortex. In conclusion, VTA MOR depletion was sufficient to prevent social defeat-induced increases of BDNF. Thus, we suggest that the VTA MORs serve as the starting point for the persistent effects of intermittent social defeat stress mediated by BDNF. These findings may have implications for stress-induced neuroplasticity and its relationship to substance abuse and mental disorders.

Title: Morphine conditioned place preference alters basal synaptic transmission in the hippocampus and amygdala and is associated with decreased synaptic NMDA receptor subunit expression.

Authors: *G. S. PORTUGAL[1], R. HASANI[2], M. R. BRUCHAS[2], J. A. MORON CONCEPCION[1]

Abstract: Associations between the rewarding properties of morphine and contextual cues can lead to cravings and increased drug-seeking behavior, which in turn may promote continued use and facilitate relapse. Glutamatergic systems, including AMPA and NMDA receptors, may play an important role in morphine-induced drug-seeking behavior such as morphine conditioned place preference (CPP), and we have previously demonstrated that context-dependent morphine treatment produces changes in AMPA receptor expression and synaptic plasticity in the hippocampus. In the present study, we used immunoblotting, electrophysiological, and behavioral techniques to investigate the effects of repeated morphine administration on AMPA and NMDA receptor expression, synaptic plasticity, and morphine CPP. Repeated morphine treatment produced a conditioned place preference for morphine when mice were tested 24 hours or one week following conditioning. This behavioral effect was associated with changes in basal synaptic transmission in the CA1 region of the hippocampus and the central nucleus of the amygdala (CeA), and impaired long-term potentiation in the hippocampus. Furthermore, preliminary results suggest that morphine CPP is associated with reduced synaptic expression of NMDA receptor subunits (NR1, NR2a, and NR2b) and additional experiments will examine alterations of AMPA and NMDA expression in the hippocampus and amygdala. These data suggest that glutamatergic synaptic transmission in the amygdala and hippocampus may play an important role in the acquisition and/or expression of morphine CPP, and future experiments will use optogenetic techniques to investigate functional interactions between the hippocampus and amygdala.

Title: Development and characterization of kappa-opioid receptor (KOR) mutant mice

Authors: A. J. BECHTHOLT-GOMPF[1], A. VAN'T VEER[1], S. ONVANI[1], D. POTTER[1], Y. WANG[2], E. H. CHARTOFF[1], U. RUDOLPH[1], L.-Y. LIU-CHEN[2], *B. M. COHEN[1], W. A. CARLEZON, Jr[1]

Abstract: Accumulating evidence indicates that kappa-opioid receptor (KOR) antagonists have antidepressant- and anxiolytic-like effects in animal models of psychiatric illness. However, prototypical KOR antagonists have unusual pharmacological properties, including a delayed and exceptionally long duration of action, that complicate data interpretation. To further evaluate the role of KORs in complex behavior, we generated KOR-mutant mice. Our mutant lines offer some advantages over those described previously because they enable (1) constitutive ablation of KORs or (2) inducible ablation in a time and region-specific manner. We flanked exon 3 (encoding transmembrane regions 2-4) of the KOR gene (Oprk1) with loxP sites. Protein lacking this region is non-functional and the excision shifts the open reading frame, ensuring that full-length protein is not made. Balb/c blastocysts were injected with IC1 C57BL/6 embryonic stem cells transfected with the targeting vector (inGenious Targeting Laboratory). After breeding out the Neo cassette (using FLP-FRT recombination) and the FLP transgene, we backcrossed the Oprk1-floxed mice (Oprk1-F/F) to C57BL/6J to congenicity (>10 generations). We then crossed these mice with mice expressing Cre recombinase ubiquitously (EIIa-Cre) and mice expressing Cre in dopamine transporter containing cells (DAT-Cre). This approach enabled us to generate global knockout mice (KOR-KO) and mice lacking KOR in DAT expressing cells (DAT/KOR-KO). We verified ablation using radioligand binding autoradiography and qPCR. As another method of verification, both lines were tested in the tail flick assay, which is sensitive to opioid-related manipulations. KOR-KO but not DAT/KOR-KO mice had decreased sensitivity to

a KOR agonist. We also tested their suitability for more complex behavioral tests by measuring visual acuity in the visual cliff assay, hearing in an acoustic startle paradigm, baseline locomotor behavior, and body weight from weaning to adulthood. KOR-KO and DAT/KOR-KO mice were normal on these measures compared to their respective wildtype (WT) littermates. Because KORs are strongly implicated in addiction, we tested both lines for sensitivity to cocaine in conditioned place preference (CPP) and locomotor sensitization tests. Although KOR ablation had no effect on cocaine-induced CPP, DAT/KOR-KO but not KOR-KO mice showed increased sensitization compared to WT controls. Our data validate our ablation technique and suggest that KORs localized on DAT-expressing neurons may normally inhibit some types of cocaine-induced plasticity.

Title: ^{1}H-mrs analysis of neurochemical response after acute treatment with the μ -opioid agonist fentanyl in mice lacking adenylyl cyclase isoforms 1 and 8

Authors: *F. GHODDOUSSI[1], N. SAWAF[2], J. LOWING[3], L. SUSICK[3], A. C. CONTI[3], M. P. GALLOWAY[1]

Abstract: Introduction: G protein coupled receptors can modulate at least 8 isoforms of adenylyl cyclases (AC) and 2 of these isoforms (AC1, AC8) are uniquely stimulated by calcium-calmodulin. Mice with a genetic deficit in AC1/8 (DKO) show an impaired behavioral response to repeated cocaine (DiRocco *et al.* 2009), methamphetamine, or morphine (Li *et al.* 2006; Zachariou *et al.* 2008). The DKO also shows prolonged ethanol-induced sedation or increased behavioral sensitivity at high doses. The fetal DKO in comparison to WT also shows increased striatal apoptosis in response to ethanol (Conti *et al.* 2009, 2010). Using ^{1}H-MRS, we investigated the acute neurochemical response to fentanyl, a potent μ-opioid agonist, in the striatum of the DKO mice.
Methods: WT and AC1/8 null mice, generated as previously described (Conti *et al.* 2009) were treated with fentanyl (25 μg/kg sc) or saline (4groups, n=6 in each group), then sacrificed 45 min later. Brains were rapidly removed, 2 mm coronal slices obtained and 1.5 mm diameter punches (3-4 mg)containing a region of interest were analyzed with magic angle spinning HR-MAS ^{1}H-MRS on an 11.7T Bruker magnet.
Results: In Rostral Medial Dorsal Striatum, in the DKO, but not WT, fentanyl decreased GABA (-26%) and glutamate (GLU, -22%) Additionally, significant decreases were noted in creatine(-17%), lactate(-25%), N-acetylaspartate(-26%) and taurine(-23%). Glutamine/GLU was increased in the DKO after Fentanyl in the same region.
Discussion: The striatal GABA and GLU response to the μ opioid agonist Fentanyl in AC1/8 null mice may be related to some of the behavioral phenotypes (e.g. hypo-activity in males) by DKO mice (described by Krishnan et al. 2008). Decreased GABA is also consistent with a key role for an AC1/8 mediated pathway regulating GABA synthesis. Moreover, our observations may be a prelude to deleterious consequences since AC1/8 are thought to provide a protective effect on synaptic homeostasis (Conti *et al.* 2010). Alternatively, decreased GABA and GLU may reflect the action of inhibitory μ opioid heteroreceptors on cortico-striatal GLU terminals or recurrent collaterals of GABA medium spiny neurons.

Title: Role of the kappa opioid system in the modulation of CeA GABAergic transmission in rats following extended access to cocaine self-administration

Authors: *M. KALLUPI[1,2], S. WEE[2], S. EDWARDS[2], T. WHITFIELD[2], C. S. OLEATA[2], G. LUU[2], G. F. KOOB[2], M. ROBERTO[2]

Abstract: It is well established that the kappa opioid system is recruited during cocaine withdrawal and is implicated in multiple withdrawal-induced anxiety-related behaviors including dysphoria and stress-induced relapse to compulsive cocaine seeking. However, little information is available about the direct interaction between the kappa opioid system and GABAergic neurotransmission in cocaine self-administering animals. Studies in our lab and others have demonstrated a keyrole of the central amygdala (CeA) in addiction. Here, using in vitro electrophysiological technique, we investigated the effects of acute cocaine and kappa opioid receptor (KOR) ligands on the GABAergic transmission in CeA of rats following limited (non compulsive ShA, 1 h/d) or extended (compulsive LgA, 6 h/d) access to cocaine self-administration. Pharmacological studies in animals with intra-CeA cannula were also employed. We found that 1) baseline evoked GABAergic transmission was enhanced in the CeA from both ShA and LgA rats compared to cocaine-naïve rats, 2) Acute cocaine application significantly decreased GABAergic responses via decreasing GABA release in both naïve and LgA rats 3) U50488, a KOR agonist, significantly decreased CeA GABAergic transmission in naïve rats, but increased their amplitudes in LgA rats, 4) nor-BNI, a KOR antagonist, significantly increased CeA GABAergic responses in naïve rats, but decreased their amplitudes in LgA rats, 5) CeA microinfusions of nor-BNI blocked cocaine-induced locomotor sensitization and 6) attenuated the heightened anxiety-like behavior observed during withdrawal from chronic cocaine exposure in the defensive burying paradigm. Our combined findings demonstrate important neuroadaptive changes induced by cocaine on the GABAergic system within the CeA and the critical role of the kappa system in cocaine sensitization and withdrawal-related behaviors. These results suggest that cocaine dynamically regulates dynorphin KOR signaling in the CeA of rats, and provides evidence that the CeA may be a key brain region in mediating the anxiolytic-like effects of KOR antagonists. Finally, the CeA kappa system may also play a role in the incentive motivational properties of cocaine.

Title: Cocaine- and morphine-induced conditioned analgesia in preweanling rats

Authors: *D. E. HUMPHREY, C. M. MARTINEZ, G. J. KAPLAN, K. L. WHITTENBURG, C. M. NUQUI, S. A. MCDOUGALL

Abstract: Mu-opioid agonists (e.g., morphine) and indirect dopamine agonists (e.g., cocaine) produce unconditioned analgesia in preweanling and adult rats. Various research groups have shown that this analgesia is mediated by both spinal and supraspinal mechanisms. When an odor cue is used, morphine will also induce conditioned analgesia in adult rats. In this paradigm, rats are repeatedly treated with saline or morphine (i.e., the unconditioned stimulus, US) in the presence of a novel odor (i.e., the conditioned stimulus, CS). On the test day, rats are exposed to the CS with no drug being administered. The presence of an analgesic response is then assessed using a standard antinociceptive test. Although it is well established that adult rats show conditioned analgesia after multiple odor-morphine pairings, it is unclear whether cocaine will induce conditioned analgesia or if this phenomenon is even evident during early ontogeny. In Experiment 1, the unconditioned analgesic effects of acutely administered cocaine (15 or 30 mg/kg, ip) and morphine (20 mg/kg, ip) were measured using a hot plate task on postnatal day (PD) 20. In Experiment 2, cocaine-induced conditioned analgesia was assessed after either one (PD 19) or four (PD 16-PD 19) conditioning days. During the conditioning phase, rats were placed in a chamber and exposed to the compound odor (i.e., the CS) of pine bedding sprinkled with 1.5 ml of banana extract. After 15 min, rats were injected with saline or cocaine (15 or 30 mg/kg) and exposed to the odor for an additional 30 min. Rats were then returned to the home cage. On the test day, which occurred 24 h later (i.e., on PD 20), all rats were injected with saline and exposed to the odor CS for 30 min. Rats were then taken to a separate room and tested on a hot plate, with paw-lick latencies and avoidance responses being recorded. Experiment 3 was conducted as just described, with the exception that saline or morphine (20 mg/kg) were injected on the conditioning days. Results showed that acutely administered cocaine (15 or 30 mg/kg) and morphine (20 mg/kg) produced unconditioned analgesia on PD 20. Morphine-induced conditioned analgesia was also evident, because rats given odor-morphine pairings on PD 19 or PD 16-PD 19 had longer paw-lick latencies than rats given odor-saline pairings. Similarly,

cocaine (15 or 30 mg/kg) produced conditioned analgesia on PD 20, and this effect occurred regardless of whether one or four odor-cocaine pairings were provided. In conclusion, rats are capable of showing cocaine- and morphine-induced conditioned analgesia during early ontogeny, with these effects being evident after a single odor-drug pairing.

Title: Novel characterization of dopamine neurotransmission following oxycodone and morphine as determined by multiple *in vivo* measurement technologies

Authors: *C. M. VANDER WEELE[1], O. S. MABROUK[2], K. A. PORTER-STANSKY[1], B. E. COUTURIER[1], V. LOVIC[1], R. T. KENNEDY[2], B. J. ARAGONA[1]

Abstract: In vivo electrochemical recordings, using fast-scan cyclic voltammetry (FSCV) to measure sub-second changes in dopamine (DA) concentration in response to intravenous opiate administration, have revealed interesting differences across drugs. Oxycodone, an opiate that acts at mu-opioid receptors, elicits the predicted increase in DA transmission within the nucleus accumbens (NAc), by robustly increasing DA concentration, transient frequency, and transient amplitude; and DA levels remain elevated for the duration of the recording period. However, morphine (another opiate and mu-opioid receptor agonist) causes changes in DA transmission that are more complex and unexpected. Within ~ 5 seconds, morphine caused an increase in DA concentration in the NAc core and shell that was quite high during the first minute; however, after this initial increase, DA concentration decreased to baseline levels (or below) soon after the infusion. Furthermore, DA concentration remained at, or below basal levels for the duration of the 15-minute recording period. This was unexpected considering previous studies using microdialysis have found that morphine generally increases DA in the NAc. However, these early microdialysis studies used longer sampling intervals. To further explore differences in DA transmission between these opiates, we utilized microdialysis with rapid sampling periods (60 s samples) coupled to novel LC-MS technology for dialysate analyses. Doses that caused similar
